

# Solution Processable Semiconducting $\text{TiO}_x$ Thin Films for Photovoltaic Applications

---

A Dissertation  
Presented to  
the faculty of the School of Engineering and Applied Science  
University of Virginia

---

In Partial Fulfillment  
of the requirements for the Degree  
Doctor of Philosophy in Electrical Engineering

by  
Jiguang Li  
August 2012

## APPROVAL SHEET

The dissertation is submitted in partial fulfillment of the  
requirements for the degree of  
Doctor of Philosophy in Electrical Engineering

Jiguang Li

Accepted for the School of Engineering and Applied Science:

J. H. Aylor

Dean, School of Engineering and  
Applied Science

August 2012

## Acknowledgment

First and foremost I would like to express my deep sense of gratitude to my advisor Professor Gupta for his tremendous technical, financial and moral support and insight throughout the years in my research. He has given me the opportunity to perform research in an exciting field at an excellent university. He has encouraged my intellectual growth. I have learned a lot of valuable skills from him.

I would like to thank Professor John Yates for his guidance. He has given me the opportunity to co-author a paper with a Nobel Prize winner. I would also like to thank Professor Lin Pu for his important suggestions and his generosity in allowing me to use his facilities to synthesize  $\text{TiO}_x$  material.

I would like to thank Professor Joe Campbell, Professor Lloyd R. Harriott and Professor John Bean for being on my annual review committee. The suggestions on my research are highly appreciated.

I would like to thank Albert DeBerardinis, Mark Turlington, Shanshan Yu and Wei Chen for their help during the material synthesis in the Chemistry department. I would also like to thank Sean Edington and Joseph Nedy for the degradation tests.

I would like to thank all of my fellow group members for their help. I want to thank Yang Shen for frequent academic discussion and support in my personal life. I want to thank Vikram Iyengar, Will Bagienski, and Vaishali Koppolu for help on problem discussions and facilities set up. I would also like to thank Dr. Chong Huang and Dr. B. K. Nayak, for helping me get started when I was new to the group. I would

also like to thank Keye Sun, Tyson Baldrige, Christian Rothenbach and Longteng Wang for their helpful discussion and experimental support.

I would like to thank Joe Beatrice, Harry Wade, Alex Lobo and Tim Pernell for clean room facility training and maintenance. I would like to thank departmental staff Dan Fetko, Yadira Weaver, Elieen Thacker, Susan Malone and Gloria Walker for their help on numerous occasions.

I would like to thank Tyson Baldrige, Yang Shen, Maggie Varland, Christian Speck, and Kiet Tran for helping me to revise this dissertation.

Lastly I would like to thank my friends and family who encouraged and supported me throughout my academic career.

## Abstract

Polymer based organic solar cells are promising due to advantages including light weight, mechanical flexibility and low cost roll-to-roll processing. Currently, organic solar cells have two major limitations, namely lower conversion efficiency and poor long-term environmental stability compared with inorganic solar cells. One method to address these limitations involves applying few tens of nanometer thin films of solution processable  $\text{TiO}_x$  in organic solar cell applications. The  $\text{TiO}_x$  thin film is used for enhancement of optical absorption and for protective coatings. The work described in this dissertation studied the properties and applications of this  $\text{TiO}_x$  material for organic photovoltaic devices.

The optical, structural, and morphological properties are important for optical applications. Optical constants were calculated by ellipsometry and modeling. X-Ray Diffraction (XRD) and Atomic Force Microscopy (AFM) were used to study the physical, structural and morphological properties. The results indicated that the sol-gel  $\text{TiO}_x$  may be used in optical thin film applications as an antireflection layer.

Electrical properties such as electrical resistivity and photoconductivity were studied. The resistivity of  $\text{TiO}_x$  was calculated as  $1.5 \times 10^7 \Omega\cdot\text{cm}$  for the as-deposited films using vertical transmission line measurement model. The thermal annealing effect and temperature dependence of the resistivity of  $\text{TiO}_x$  thin films were also investigated.

The degradation of the PCBM/P3HT organic solar cell was studied under different UV light intensities and gas environments. Transmission infrared (IR) and Electron Spin Resonance (ESR) spectroscopies were used to study the chemical changes

of the  $\text{TiO}_x$  thin films under different conditions. The results suggested that the photochemical removal of  $\text{O}_2$  by  $\text{TiO}_x$  films passivated the organic solar cells from oxygen induced degradation. The protection capacity by  $\text{TiO}_x$  films was calculated. Distribution of the local photocurrent in the cells with and without  $\text{TiO}_x$  protection layers were obtained by laser beam induced current measurements. The results demonstrated that the introduction of the  $\text{TiO}_x$  layer could effectively absorb water/oxygen from ambient air.  $\text{TiO}_x$  thin films protected the cells at the edge of the devices.

Further improvement of the  $\text{TiO}_x$  material properties was achieved by doping. Fe doped  $\text{TiO}_x$  material improves the organic solar cell efficiency while Cs doping does not benefit efficiency. The photovoltaic characteristic parameters such as efficiency, open circuit voltage, short circuit current and fill factor are reported.

The application of the  $\text{TiO}_x$  material on inorganic Si solar cells was also explored. Silicon solar cells using  $\text{TiO}_x$  thin films for surface passivation and anti-reflection coatings were successfully fabricated. The obtained efficiency of 15.7 % is comparable with devices using  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  as passivation and anti-reflection layers, respectively. The passivation effects were evaluated by near surface lifetime measurements.

This work covers the measurements of the fundamental optical and electrical properties, protection mechanism, modification and application of the  $\text{TiO}_x$  material.

## Table of Contents

|   |    |
|---|----|
| Chapter 1. Background.....  | 1  |
| 1.1 Photovoltaic .....  | 1  |
| 1.2 Titanium dioxide (TiO <sub>2</sub> ) material.....                                    | 4  |
| 1.2.1 TiO <sub>2</sub> properties .....   | 4  |
| 1.2.2 TiO <sub>2</sub> thin films applications .....                                      | 4  |
| 1.2.3 TiO <sub>2</sub> thin films fabrication .....                                       | 5  |
| 1.3. TiO <sub>x</sub> material .....  | 5  |
| 1.3.1 TiO <sub>x</sub> material properties.....   | 5  |
| 1.3.2 TiO <sub>x</sub> thin films for protection of organic solar cells degradation ..... | 6  |
| 1.3.3 TiO <sub>x</sub> thin films for Si solar cells .....                                | 6  |
| 1.4 Objective of the research.....  | 7  |
| 1.5 Organization of the dissertation .....  | 8  |
| Chapter 2. TiO <sub>x</sub> precursor synthesis and thin films fabrication .....          | 11 |
| 2.1 TiO <sub>x</sub> precursor synthesis .....  | 11 |
| 2.2 TiO <sub>x</sub> thin films fabrication.....  | 12 |
| 2.2.1 Hydrolysis and condensation.....  | 12 |
| 2.2.3 Coating morphology.....   | 17 |
| 2.3 Summary .....   | 18 |
| Chapter 3. Optical properties of TiO <sub>x</sub> thin films .....                        | 19 |
| 3. 1. Introduction .....  | 19 |
| 3. 2. Experiment .....  | 19 |
| 3.2.1. Thin films preparation .....   | 19 |
| 3.2.2. Sample characterization .....  | 20 |
| 3.3. Results and discussion .....   | 21 |
| 3.3.1. Optical constant .....   | 21 |
| 3.3.2 Film thickness.....   | 26 |
| 3.3.3 Surface morphology .....  | 26 |
| 3.3.4. Crystalline structure .....  | 28 |
| 3.3.5. Optical reflectance .....  | 31 |
| 3. 4. Conclusions .....   | 32 |

|   |    |

## Chapter 1. Background

### 1.1 Photovoltaic

With the rising concerns of fossil fuel depletion and global warming, there is a growing demand for renewable and clean energy sources. Photovoltaic (PV) cells are one of the most promising choices. Of all the renewable resources, solar is by far the most abundant <sup>[1]</sup>. Photovoltaic solar power has several advantages. For example, photovoltaic cell modules produce no emissions and can be installed and operated anywhere including remote locations and areas with poor accessibility.

Photovoltaics are also currently one of the most expensive sources of renewable energy. Two categories of PV cells are used in most commercial PV modules: crystalline silicon and thin film. The crystalline silicon PV cells are the most efficient of the mainstream PV technologies and accounted for about 84% of PV cells produced in the world in 2008 <sup>[2]</sup>.

Higher-efficiency modules require less installation area per watt of electricity production than lower-efficiency modules. Photovoltaic modules have undergone significant cost reductions over the last few decades, which is illustrated in Figure 1-1<sup>[2]</sup>, and shows the average global PV module selling prices for all PV technologies. Thin-film PV technologies achieved lower manufacturing costs and selling prices than crystalline silicon modules.

Figure 1-1: Global, average PV module prices, all PV technologies, 1984-2010,  $\$/W_p$  stands for the prices that are not adjusted for inflation. 2010  $\$/W_p$  stands for the prices that are adjusted for inflation <sup>[2]</sup>.

The price is affected by many factors such as efficiency. The current estimated effect is a \$0.10 increase in price per 1 % increase in efficiency. One way to reduce the cost is to simplify the processing techniques. Currently, Si solar cell fabrication requires special processes. For example, the anti-reflection coating and surface passivation are achieved by depositing silicon nitride using plasma enhanced chemical vapor deposition (PECVD). However, PECVD deposition is time consuming and relatively expensive. Alternatively, solution processable techniques can be cost effective for anti-reflection and surface passivation.

Organic solar cells offer the potential for substantial manufacturing cost reductions. Organic semiconductors have relatively strong absorption coefficient (usually  $>10^5 \text{ cm}^{-1}$ ) [1]. Therefore they offer the possibility for the production of very thin solar cells with low specific weight. Organic solar cells can be manufactured using highly efficient ink-jet printing. Organic semiconductors can also be deposited on thin flexible substrates that enable integration within products while keeping the weight low. Concisely, low manufacturing costs can be attained by processing photovoltaic modules with large-area manufacturing technologies such as high-throughput roll-to-roll printing techniques onto flexible substrates.

One of the most promising device structures for organic solar cells is the bulk-heterojunction, which leads to several breakthroughs in efficiency, reaching 10.6 % [3]. It composes the blend of a hole-conducting and electron-donating conjugated polymer, such as the low-bandgap conjugated polymer: poly{2,6'-4,8-di(5-ethylhexylthienyl)benzo[1,2-b;3,4-b]dithiophene-alt-5-dibutyloctyl-3,6-bis(5-bromothiophen-2-yl)pyrrolo[3,4-c]pyrrole-1,4-dione} (PBDTT-DPP), and an electron-conducting and electron-accepting compound, such as [6,6]-phenyl-C<sub>71</sub>-butyric acid methyl ester (PC<sub>71</sub>BM).

The short operational stability and lifetime remain as the key issues of organic solar devices. The organic devices are vulnerable to the diffusion of ambient oxygen or humidity into the active layer. The devices degrade quickly when exposed to air. Improvement of stability that could comply with concepts such as the simple fabrication by solution processing, flexibility, and thin form factor are desired for further progress.

Recently, Heeger's group demonstrated that novel sol-gel TiO<sub>x</sub> thin films could dramatically increase the efficiency and lifetime of organic solar cells by using it as an

optical spacer, hole blocking layer, and oxygen protecting layer <sup>[4, 5, 6]</sup>. In this project, we explore this novel solution processable semiconducting  $\text{TiO}_x$  thin films for low cost photovoltaic applications through investigation of fundamental properties, protection mechanism, and modification of the  $\text{TiO}_x$  materials.

## **1.2 Titanium dioxide ( $\text{TiO}_2$ ) material**

### **1.2.1 $\text{TiO}_2$ properties**

$\text{TiO}_2$  is a relatively abundant material, existing in nature as the minerals in rutile, anatase, and brookite.  $\text{TiO}_2$  thin films are generally amorphous for low deposition temperatures ( $\leq 350^\circ\text{C}$ ). The properties of  $\text{TiO}_2$  thin films strongly depend on the phase of the material and processing techniques. Typically,  $\text{TiO}_2$  has high electrical resistance with resistivity of  $10^{14} \Omega \text{ cm}$  <sup>[7]</sup>. It shows excellent optical transmittance in the visible region.

The electrical conductivity, photoconductivity, and structural and optical properties of  $\text{TiO}_2$  made using different processing techniques and conditions have been extensively studied.

### **1.2.2 $\text{TiO}_2$ thin films applications**

$\text{TiO}_2$  thin films have been extensively used in optical device applications, including planar waveguides <sup>[8]</sup>, diffraction gratings <sup>[9]</sup>, self-cleaning optical coatings <sup>[10]</sup>, infrared detectors <sup>[11]</sup>, and electrochromic displays <sup>[12]</sup>.

The high refractive index and low absorbance at visible wavelengths make  $\text{TiO}_2$  well suited for solar cells applications, such as anti-reflection coatings <sup>[13]</sup>, surface

passivation <sup>[14]</sup>, transparent conducting oxide layers <sup>[15]</sup>, and transparent electrodes in dye sensitizer solar cells <sup>[16]</sup>.

### **1.2.3 TiO<sub>2</sub> thin films fabrication**

Various methods are available for the fabrication of the TiO<sub>2</sub> films, including the sol-gel method <sup>[17,18]</sup>, electron-beam evaporation <sup>[19]</sup>, electrodeposition <sup>[20]</sup>, plasma enhanced chemical vapor deposition (PECVD) <sup>[21,22]</sup>, sputtering <sup>[23]</sup>, atmospheric pressure chemical vapor deposition (APCVD) <sup>[24]</sup>, laser ablation <sup>[25]</sup>, ion assisted deposition <sup>[26]</sup>, and ultrasonic spraying <sup>[27]</sup>. The properties of the TiO<sub>2</sub> films can be modified by different processing conditions.

The sol-gel method is one of the most promising techniques. It is a simple and low cost process. TiO<sub>2</sub> can be synthesized numerous ways. For example, Phadke et al. produced TiO<sub>2</sub> thin films by spin coating a solution made from titanium isopropoxide, acetic acid and 1-butanol on silicon substrates <sup>[17]</sup>. Sankapal et al. used titanium peroxide (titanium peroxy-complex) as a titanium source to produce nanocrystalline TiO<sub>2</sub> (anatase) thin films <sup>[18]</sup>. Kaewwiset et al. prepared TiO<sub>2</sub> sol-gel from titanium tetra isopropoxide in isopropanol by adjusting the pH of the solution using nitric acid <sup>[28]</sup>.

## **1.3. TiO<sub>x</sub> material**

### **1.3.1 TiO<sub>x</sub> material properties**

The TiO<sub>x</sub> produced by Heeger's group contains Ti : O = 42.1:56.4 as determined by X-ray photoelectron spectroscopy (XPS) measurement <sup>[6]</sup>. TiO<sub>x</sub> material contains ...Ti-O-Ti... interpenetrating structures. The uniform dense TiO<sub>x</sub> films are

semiconducting. In  $\text{TiO}_x$ , the electron mobility is higher as compared to the amorphous oxide films prepared by the typical sol-gel processes. The sol-gel precursor is stable, can be used for coatings after synthesis, and does not require any acid catalyst unlike the previously mentioned work.

### **1.3.2 $\text{TiO}_x$ thin films for protection of organic solar cells degradation**

Degradation of organic solar cells in general has been investigated by several groups. Kwano et al. showed that water absorption by the PEDOT: PSS layer accounted for some of the observed degradation <sup>[29]</sup>. Reese et al. concluded that the metal/organic interface can be a major source of degradation <sup>[30]</sup>. Gevorgyan et al. reported that the degradation mechanism in ambient atmosphere was related to chemical reactions of the active layer and metal electrodes with  $\text{O}_2$  and  $\text{H}_2\text{O}$  <sup>[31]</sup>. The decay of organic solar cells is complex and may involve several mechanisms.

Different approaches of achieving higher stability have been considered, such as using improved active materials and encapsulation schemes. Lee et al. demonstrated the enhanced stability of polymer light emitting diodes and polymer solar cells by incorporating a solution processable  $\text{TiO}_x$  layer between the active layer and the metal electrode <sup>[5]</sup>.  $\text{TiO}_x$  has been used to block the passage of oxygen and humidity into active layer. The  $\text{TiO}_x$  layer provided the protection from  $\text{O}_2$  and  $\text{H}_2\text{O}$ .

### **1.3.3 $\text{TiO}_x$ thin films for Si solar cells**

Various groups have studied titanium dioxide ( $\text{TiO}_2$ ) films deposited by CVD, sputtering and sol-gel methods for anti-reflection and surface passivation <sup>[32,33,34]</sup>. The surface passivation of silicon is usually accomplished by annealing the  $\text{TiO}_2$  layer in an

oxygen rich atmosphere which leads to the formation of an interfacial silicon dioxide layer. The other mechanism of surface passivation can be due to the accumulation of interfacial charges, either positive or negative, depending on the stoichiometry<sup>[35]</sup> of the films or light-induced effects. The most notable one being in 1987 where the authors evaporated Ti in an oxygen ambient<sup>[36]</sup>. There are few reports, however, which demonstrate the incorporation of solution processable TiO<sub>x</sub> films for surface passivation and an anti-reflection coating, and its application for silicon solar cells.

#### **1.4 Objective of the research**

The objective of the research is to study TiO<sub>x</sub> materials for photovoltaic applications. Optical and electrical properties are critical in photonic devices for the light absorption and carrier transport. Therefore, we studied the optical and electrical properties of TiO<sub>x</sub>. The optical properties of TiO<sub>x</sub> thin films were investigated as a function of wavelength using ellipsometric and optical reflection technique. The XRD and AFM were used to study the TiO<sub>x</sub> phase, density and morphology changes under thermal annealing. The electrical resistivity of solution processable semiconducting TiO<sub>x</sub> thin films was investigated. TiO<sub>x</sub> bulk resistance and contact resistance were extracted from the vertical transmission line measurement model. Temperature dependence of the electrical resistivity and the variation of electrical resistivity with different annealing temperature will be studied.

To verify the postulation that photo-oxidation of the bound organic moieties causes oxygen gas scavenging, we examined the individual effect of oxygen and UV radiation as well as their combined effect on the degradation behavior of P3HT/PCBM organic solar cell devices and the improvements provided by placing the TiO<sub>x</sub> layer

between the active layer and a metal electrode. IR and ESR spectroscopy measurements were used to examine the chemical composition of the films.

Laser beam induced current mapping was used to obtain the local current distribution of the device with/without  $\text{TiO}_x$  protection. This data improves the understanding of the protection mechanism.

The modification of the  $\text{TiO}_x$  material was explored since the  $\text{TiO}_x$  layer changes the series resistance of the organic solar cells. Doping the metal oxide can improve the electrical properties of the material. We examined the doping effects of Cs and Fe doping on  $\text{TiO}_x$  material as well as the effects on the organic solar cell performance.

The application of solution processable  $\text{TiO}_x$  thin films for silicon solar cells was studied.  $\text{TiO}_x$  thin films were used as anti-reflection and passivation layers. The surface passivation quality of these films was evaluated by surface lifetime measurement.

## **1.5 Organization of the dissertation**

This dissertation is organized in 10 chapters as follows:

Chapter 1 gives a brief introduction of the photovoltaic market and the basic properties of  $\text{TiO}_2$  and  $\text{TiO}_x$  material.

Chapter 2 describes the  $\text{TiO}_x$  precursor synthesis and thin films fabrication. The  $\text{TiO}_x$  thin films were formed through hydrolysis and condensation. The humidity effects on the hydrolysis process were studied by infrared (IR) spectroscopy.

Chapter 3 details the optical properties of  $\text{TiO}_x$  thin films. The optical constants of the  $\text{TiO}_x$  films were studied by ellipsometric technique and 3-layer modeling. Crystalline structure and surface morphology were examined to explore the origin of the changes of optical constants of  $\text{TiO}_x$  thin films.

Chapter 4 provides the electrical resistivity of  $\text{TiO}_x$  thin films, including electrical resistivity of as-deposited films, temperature dependence of electrical resistance of  $\text{Al/TiO}_x/\text{ITO}$  structure, thermal annealing effect on  $\text{TiO}_x$  thin films and photoconductivity under UV illumination.

Chapter 5 gives the introduction of organic solar cells, such as the development of polymer solar cells, operating principle, donor/acceptor materials and characterization parameters for organic solar cells. The device structure and fabrication of polymer solar cells used in this dissertation are introduced.

Chapter 6 presents a study of stabilization of P3HT/PCBM organic solar cells by a photochemically active  $\text{TiO}_x$  layer. Degradation and improvements by  $\text{TiO}_x$  of organic solar cells under different condition is shown. The photovoltaic characterization parameters are analyzed. The protection mechanism is investigated using IR and ESR spectroscopy techniques. Protection capacity is calculated.

Chapter 7 presents further study on the  $\text{TiO}_x$  protection using a laser beam induced current mapping technique. The efficiency patterns, island formation and comparison of devices with/without  $\text{TiO}_x$  protection are analyzed.

Chapter 8 shows the results on doping  $\text{TiO}_x$  material with Fe and Cs for further improvement, such as the doping effects on  $\text{TiO}_x$  resistivity and organic solar cell performance.

Chapter 9 describes the application of  $\text{TiO}_x$  thin films in Si solar cells. The photovoltaic device characterization results for Si solar cells with  $\text{TiO}_x$  thin films as a surface passivation and anti-reflection coating are shown. Surface passivation is evaluated using results from the near-surface lifetime measurement technique.

Chapter 10 summarizes the work in this project and shows some possible directions for future work.

## Chapter 2. **TiO<sub>x</sub> precursor synthesis and thin films fabrication**

### **2.1 TiO<sub>x</sub> precursor synthesis**

The TiO<sub>x</sub> material is synthesized using sol-gel chemistry according to reference <sup>[4]</sup>. The experimental set up is shown in Figure 2-1. All the glassware was left in a heating oven overnight to remove moisture.

The sol-gel procedure started with the injection of titanium isopropoxide [Ti (OCH (CH<sub>3</sub>)<sub>2</sub>)<sub>4</sub>] (Aldrich, 99.999 %, 2 ml), 2-methoxyethanol [CH<sub>3</sub>OCH<sub>2</sub>CH<sub>2</sub>OH] (Aldrich, 99.9+ %, 8 ml) and ethanolamine [H<sub>2</sub>NCH<sub>2</sub>CH<sub>2</sub>OH] (Aldrich, 99.5+ %, 0.8 ml) one by one into a three-necked flask connected with water condensers and a nitrogen gas inlet at room-temperature. The mixed solution was stirred for 1 hour at room-temperature. Then it was heated at 80 °C for 1 hour, followed by heating to 120 °C for 1 hour until the solution was transformed to a low-density viscous gel with a dark wine color. The inside of the flask was supplied with continuous dry N<sub>2</sub>, and the mixed solution was stirred continuously during the experiment. After cooling to room temperature, 4 ml methanol was injected to extract the final TiO<sub>x</sub> sol-gel product.

Figure 2-1: Experimental set up for  $\text{TiO}_x$  precursor synthesis

## 2.2 $\text{TiO}_x$ thin films fabrication

### 2.2.1 Hydrolysis and condensation

Hydrolysis and condensation occurs when the  $\text{TiO}_x$  sol-gel is taken out into air, which contains water molecules, resulting in the formation of  $\text{Ti-O-Ti}$  linkages. These reactions occur slowly in the solution form, because the methanol solution inhibits the interaction of the  $\text{TiO}_x$  with moisture in the ambient environment. The reactions are significantly accelerated, however, after spin casting to form thin solid films.

At present, the hydrolysis reaction scheme proposed by Livage<sup>[37]</sup> is generally accepted. The first step comprises substitution of one alkoxy group with a hydroxy group by a nucleophilic mechanism:

In the second step, -Ti-O-Ti- bridges form during the course of condensation reactions:

The thickness of the films can be controlled by adjusting sol-gel concentration and the spinning speed.

The water molecules act as a catalyst in the hydrolysis process. Therefore humidity affects the reaction speed of the hydrolysis process. The C-H components in the -OR group should evaporate after hydrolysis. Therefore we can monitor the C-H component to characterize the hydrolysis process.

Fourier transform infrared spectroscopy (FTIR) is a useful tool for identifying types of chemical bonds (functional groups). FTIR can be used to identify chemical groups in spills, paints, polymers and coatings. The wavelength of light absorbed is characteristic of the chemical bond. By interpreting the infrared absorption spectrum, the chemical bonds in a molecule can be determined.

The experiment setup for the humidity effect measurement is described as follows:

The TiO<sub>x</sub> material was dissolved to 10 % by volume in methanol, and used at room temperature to spin coat ~ 200 nm films onto a CaF<sub>2</sub> single crystal disk, which is transparent in the visible-infrared wavelength. The CaF<sub>2</sub> disk was 25 mm in diameter and 5 mm in thickness. Transmission IR measurements were made with a Nicolet Avatar 330 FT-IR spectrometer.

Two samples were made to compare the hydrolysis process in high and low humidity environments. One sample stayed in normal condition. The humidity was measured as 40 % by humidity meter. Another sample was put on the top of a humidifier, which generates water vapors at room temperature. The humidity was measured as 70 %.

The FTIR spectrum of spinning coated  $\text{TiO}_x$  film is shown in Figure 2-2. C-H bonds peak appears around 3000-2750 wave number ( $\text{cm}^{-1}$ ), as shown in the black circle region in the Figure. This C-H bond peak region is the characteristic of the alkoxide functional groups remaining in the  $\text{TiO}_x$  films. The absorbance indicates the quantity of the C-H bonds in the films.

Figure 2-2: The FTIR spectrum of spin coated  $\text{TiO}_x$  film

The FTIR spectrum after hydrolysis process is shown in Figure 2-3. The C-H bond position is basically identical for the two fresh samples right after spin coating, as shown in Figure 2-3 (a). There are obviously differences after 30 minutes in different humid environment, as shown in Figure 2-3 (b). The absorbance of the C-H bonds region

is lower for the sample in the high humidity environment. This indicates the hydrolysis process is faster in the high humidity environment. There are still differences for the samples after 4 hours in different humid environments, as shown in Figure 2-3 (c). However, the spectrums of the two samples become similar after 20 hours, as shown in Figure 2-3 (d), which indicates that the hydrolysis is complete. The time frame is consistent with the hydrophobic/hydrophilic measurement reported by Heeger's group <sup>[4]</sup>.

Figure 2-3: The FTIR spectrum of  $\text{TiO}_x$  films on  $\text{CaF}_2$  during hydrolysis process. Blue line represents the sample in the high humidity environment; red line represents the

sample in the high humidity environment. (a) Fresh sample (b) Hydrolysis process for 30 minutes (b) Hydrolysis process for 4 hours (d) Hydrolysis process for 20 hours

### 2.2.3 Coating morphology

The  $\text{TiO}_x$  sol gel can be spin-coated on flat substrates such as silicon, quartz, glass and so on. It forms uniform thin films as shown in Figure 2-4 (a).

The spin-coating process on the P3HT: fullerene active layer surface is not straightforward. Because of hydrophobicity of P3HT (particularly alkyl chain of P3HT), wetting is not good. To obtain good  $\text{TiO}_x$  films on the surface of P3HT: fullerene active layer, waiting for approximately 1 min is required after dropping the  $\text{TiO}_x$  solution, then the spinning starts.

The  $\text{TiO}_x$  thin films also conform well to the chemically textured silicon surface as shown in the SEM image in Figure 2-4 (b). Placing a spin-coated sample directly on an 80 °C hot plate led to cracked films with poorer quality. Coating thicker films in a single step leads to solution accumulation between texture cones and severe cracking of the films was observed. Therefore ramp heating and thin layer coating were used to achieve uniform coating. A 20 nm  $\text{TiO}_x$  film was spin-coated followed by ramp soft-baking from 25 °C to 80 °C in 20 minutes. Next, an additional 20 nm of  $\text{TiO}_x$  film was spin-coated followed by soft-baking.

Figure 2-4: (a) Optical image of a polished silicon surface spin coated with  $\text{TiO}_x$  film and (b) SEM image of a chemically textured silicon surface coated with  $40\ \text{nm}$  of  $\text{TiO}_x$  film

### 2.3 Summary

In this chapter, we described the synthesis and thin film fabrication of the  $\text{TiO}_x$  material. The effect of humid on the hydrolysis process in thin film formation was studied. The hydrolysis process was accelerated in the high humidity environment. The coating properties on different substrates were also characterized.

## Chapter 3.      **Optical properties of $\text{TiO}_x$ thin films**

### **3. 1. Introduction**

As stated in chapter 1, titanium dioxide ( $\text{TiO}_2$ ) thin films have been extensively used in optical device applications. Various methods are available for the fabrication of the  $\text{TiO}_2$  films, including sol-gel method, electron-beam evaporation, electro-deposition and PECVD. The properties of the  $\text{TiO}_2$  films can be modified by different processing conditions, as a consequence, the optical properties of thin films change. Sol-gel method is one of the most promising techniques. It is simple and low cost process.

This chapter presents the measurement results of the optical properties of  $\text{TiO}_x$  thin films. The variation of refractive index of thin films was measured through ellipsometry and modeling. The AFM was used for measuring the surface morphology and thicknesses of the films. Further study of X-ray diffraction was conducted to explore the crystalline nature of the films.

### **3. 2. Experiment**

#### **3.2.1. Thin films preparation**

The  $\text{TiO}_x$  material is synthesized using sol-gel chemistry as described in chapter 2. P-type (1 0 0), 1 ohm-cm silicon wafers were used as substrate. The Si wafer was dipped in buffered oxide etchant (BOE) for 10 minutes to remove the native silicon oxide layer. The  $\text{TiO}_x$  precursor solution was then spin-coated on the Si substrate in air. The sample was baked in air at 90 °C for 10 minutes. The precursor was converted to  $\text{TiO}_x$  by hydrolysis.

Annealing was carried out in a rapid thermal annealing (RTA) chamber to study the variation of optical properties under different annealing temperatures and environment. The samples were annealed under O<sub>2</sub> or forming gas (mixture of N<sub>2</sub> and 5.05% H<sub>2</sub>) for 10 minutes at 400 °C, 500 °C, 700 °C and 900 °C.

### **3.2.2. Sample characterization**

The measurement of a multi-wavelength refractive index was carried out using an ellipsometer at an angle of incidence of 70 °. Ellipsometer is an optical technique for the investigation of the dielectric properties of thin films. The reflection at a dielectric interface depends on the polarization of the light. The transmission of light through a transparent layer changes the phase of the incoming wave depending on the refractive index of the material. An ellipsometer measures the changes in the polarization state of light when it is reflected from a sample. Then the optical constants can be extracted. The ellipsometer used in this work is a Jobin Yvon UVISSEL NIR Spectroscopic Phase Modulated Ellipsometer. The data was obtained from 350 nm to 800 nm.

The thickness of the spin coated films was also measured using AFM. AFM measures the height between substrate and the top of the TiO<sub>x</sub> films.

The surface morphology of the films was investigated by Dimension Nanoscope 3100 AFM. AFM was set to non-contact scanning probe microscopy mode. Scanning of the sample surface was taken before and after annealing, and root mean square (RMS) surface roughness was calculated.

The structure and crystallinity of the films were determined by a Scintag automated XDS 2000 XRD system. The measurement was conducted at room temperature.

The reflectance of various  $\text{TiO}_x$  thin films on Si substrate was measured by Filmetrics Filmeasure tool Version 2.1.2.

### 3.3. Results and discussion

#### 3.3.1. Optical constant

The optical constants of the  $\text{TiO}_x$  thin films layer are simulated with Bruggemann effective medium approximation <sup>[38,39,40]</sup>. A three layer films structure model was established in order to determine the optical constants of the films by ellipsometric method. The model consists of a Si substrate, a dense  $\text{TiO}_x$  layer and a 50 %  $\text{TiO}_x$ : 50 % void surface layer, as shown in Figure 3-1. The mixture of  $\text{TiO}_x$  and void layer simulates the surface roughness. This model has been widely used and it agrees well with the experimental data <sup>[38]</sup>.

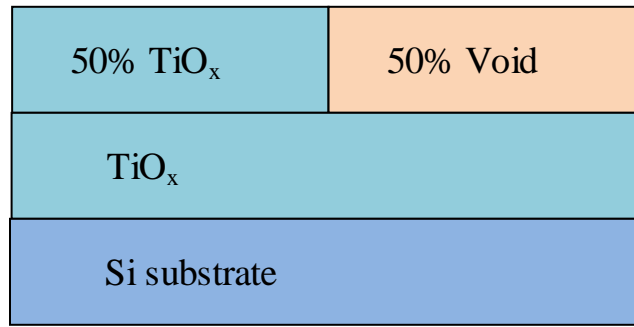

Figure 3-1: Three layers model of  $\text{TiO}_x$  films <sup>[41]</sup>

The dispersion model used to describe the  $\text{TiO}_x$  material is based on the original Forouhi-Bloomer formula <sup>[42]</sup>. This formula is consistent with the Kramers–Kronig analysis, which works well for a broad wavelength range. In this work, we calculated the optical constants in the visible range (from 350 nm to 800 nm) using equation (3-1).

$$n = n_{\infty} + \frac{B(\omega - \omega_0) + C}{(\omega - \omega_0)^2 + \Gamma^2}, \quad k(\omega) = \begin{cases} 0, (\omega \leq \omega_g) \\ \frac{f(\omega - \omega_0)^2}{(\omega - \omega_0)^2 + \Gamma^2}, (\omega > \omega_g) \end{cases} \quad (3-1)$$

where  $B = \frac{f}{\Gamma}(\Gamma^2 - (\omega - \omega_g)^2)$ ,  $C = 2\Gamma f(\omega - \omega_g)$ .

$n_{\infty}$  is a constant greater than 1. The value depends on particular material <sup>[43]</sup>.  $\omega$  is the photon energy.  $\omega_g$  is the optical gap energy.  $\omega_0$  is the bonding–antibonding states energy difference, the absorption is assumed to be maximum for this photon energy. The quantity  $f$  is related to the position matrix element and lifetime of the electrons involved in the optical transitions.  $\Gamma$  is related to the life time of the electrons involved in the optical transitions.  $B$  and  $C$  are not mere fitting parameters, but are related to electronic structure of the material. Detailed explanation of these parameters can be found in reference <sup>[42]</sup>.

All modeling of optical constants was performed using the Jobin Yvon DeltaPsi2 (DP2) software package. The calculated parameters from the model fitting of experimental data are shown in Table 3-1.

Table 3-1: Modeling parameters for refractive index simulation

| Annealing condition /parameters | 900 °C in O <sub>2</sub> | 700 °C in O <sub>2</sub> | 400 °C in O <sub>2</sub> | As deposited | 400 °C in forming gas | 700 °C in forming gas | 900 °C in forming gas |
|---------------------------------|--------------------------|--------------------------|--------------------------|--------------|-----------------------|-----------------------|-----------------------|
| $n_{\infty}$                    | 2.3                      | 2.30                     | 2.21                     | 1.65         | 2.16                  | 2.10                  | 2.03                  |
| $\omega_g$ (eV)                 | 3.08                     | 3.22                     | 3.24                     | 3.30         | 3.26                  | 3.25                  | 3.20                  |

|               |      |      |      |      |      |      |      |
|---------------|------|------|------|------|------|------|------|
| f             | 0.24 | 0.20 | 0.03 | 0.07 | 0.02 | 0.28 | 0.34 |
| $\omega$ (eV) | 3.98 | 3.91 | 3.55 | 4.55 | 3.63 | 4.28 | 4.20 |
| $\Gamma$ (eV) | 0.39 | 0.36 | 0.13 | 0.41 | 0.16 | 0.65 | 0.54 |

Figure 3-2 (a) and 3-2 (b) show the measured refractive index changes when the sample is annealed in forming gas and O<sub>2</sub>, respectively. The data show that the refractive index increases with the annealing temperature.

The annealing process increases the refractive index. The increase of the refractive index is due to complex changes of organic component removal, film density changes and changes due to crystalline phase and surface morphology.

The refractive index increases from 1.77 to 2.57 at a wavelength of 600 nm after annealing at 900 °C. This is close to what was reported in publications for the TiO<sub>2</sub> films. After annealing at 700 °C and 900 °C, the refractive index of samples annealed in O<sub>2</sub> is higher than the one annealed in forming gas.

The variation of extinction coefficient  $k$  with wavelength is shown in Figure 3-2 (c) and 3-2 (d) when TiO<sub>x</sub> films are annealed at various temperatures in forming gas and O<sub>2</sub>, respectively.

The annealing process increases the extinction coefficient. The as deposited TiO<sub>x</sub> films prepared at room temperature contains short -Ti-O-Ti- structures within the film, leading to electron confinement and an electronic gap which is broader than for the infinite -Ti-O-Ti- entities within bulk TiO<sub>2</sub>. TiO<sub>2</sub> in bulk anatase or rutile crystal phases exhibits a band gap of ~3.1 eV. The -Ti-O-Ti- structure develops into longer more organized structures as organic matter and water are removed from the film by thermal

annealing. In these annealed structures, electron confinement effects are reduced. Therefore the  $\text{TiO}_x$  shows a high extinction coefficient around 400 nm after annealing. The extinction coefficient is close to zero in most of the wavelength range from 350 nm to 800 nm.

### 3.3.2 Film thickness

It has been reported that there is a direct relationship between the refractive index and the density of the films <sup>[44]</sup>. Removal of the organic residue material and densification of the films occurs during the annealing process. The TiO<sub>x</sub> films thickness is reduced after high temperature annealing. The layer thicknesses under different annealing conditions are listed in Table 3-2.

Table 3-2: Layer thickness at different thermal annealing conditions

| Layer thickness (nm)   | 900 °C in O <sub>2</sub> | 700 °C in O <sub>2</sub> | 400 °C in O <sub>2</sub> | As deposited | 400 °C in forming gas | 700 °C in forming gas | 900 °C in forming gas |

### 3.3.3 Surface morphology

Surface morphology will affect optical constants due to the light reflection, absorption and scattering. Therefore changes of the surface morphology contribute to the variations in the effective refractive index. The surface morphology is studied by AFM.

Figure 3-3 (a) shows the surface morphology of as-deposited films obtained using AFM. The surface roughness of the bare silicon substrate is 0.24 nm. As deposited sample shows smooth surface with surface roughness of 1.5 nm which is evaluated from 10  $\mu\text{m}$   $\times$  10  $\mu\text{m}$  surface areas. The surface becomes rougher after annealing, as indicated in Figures 3-3 (b) and 3-3 (c) , which show the surface morphology of samples annealed

in O<sub>2</sub> and forming gas at 900 °C for 10 minutes, respectively. The surface roughness increases to 2.5 nm.

It is noted that the surface roughness increases with the appearance of the crystalline phase by comparing with the crystalline phase change shown in Figure 3-4. Small grains can be observed on the surface by AFM. The morphology changes are due to the crystallization of TiO<sub>x</sub> and densification of the films.

(a)

(b)

(c)

Figure 3-3: (a) AFM image of as deposited film (b) AFM image of film annealed in O<sub>2</sub> at 900 °C for 10 minutes (c) AFM image of film annealed in forming gas at 900 °C for 10 minutes<sup>[41]</sup>

#### 3.3.4. Crystalline structure

Crystalline phase changes affect the refractive index. Crystallization occurs during the high temperature rapid thermal annealing process. Crystalline structure changes the refractive index. Rutile phase has different refractive index than anatase phase of TiO<sub>2</sub> <sup>[45]</sup>. The annealed films could be composed of amorphous, anatase and rutile structures. The results on phase changes after annealing process are discussed in this section.

Depositing TiO<sub>x</sub> thin films onto substrates at low temperature leads to an amorphous structure. High temperature induces crystallization for the amorphous material. The titanium to oxygen ratio (Ti: O = 42.1: 56.4) indicates the sub-oxide characteristics of the as deposited TiO<sub>x</sub>. Thermal annealing treatment promotes conversion of sub-oxide to dense crystalline structure. The effects of the thermal annealing on crystalline phase changes were examined.

The XRD results shown in Figure 3-4 indicate different phases of the films. The increase in annealing temperature could result in more observable crystalline phases. Figure 3-4 (a) and 3-4 (b) show the crystalline structure changes with temperature when annealed in forming gas and O<sub>2</sub>, respectively. The as-deposited films show amorphous structure without any crystalline peak. The peaks at  $2\theta = 33^\circ$  and  $2\theta = 70^\circ$  are from Si substrate. They are the Si (1 0 0) and Si (4 0 0) peaks, respectively. The anatase (1 0 1) peak at  $2\theta = 25.6^\circ$  was observed at 500 °C when annealed in O<sub>2</sub>. It indicates that crystalline structure appears in the film after annealing. No anatase peak was observed for the sample annealed at 500 °C in forming gas. The rutile (1 1 0) peak of TiO<sub>2</sub> material at  $2\theta = 27.5^\circ$  was observed after annealing in O<sub>2</sub> at 700 °C. This peak corresponds to the rutile phase. The anatase phase peak disappears. It indicates that the films are transformed to a crystalline form with a rutile-dominant phase at high temperature. Anatase phase is a metastable phase at low temperatures. Therefore it is reasonable that the films were crystallized in a rutile-type structure at high temperature instead of the anatase-type structure. Similar rutile crystal structure was also clearly observed for the films annealed in forming gas at 900 °C. It suggests that annealing in O<sub>2</sub> and forming gas will induce different Ti: O composition during the high temperature process. It is easier to form crystalline TiO<sub>2</sub> structure in rich oxygen environment.

(a)

(b)

Figure 3-4: The XRD spectra for  $\text{TiO}_x$  films annealed in (a) forming gas and (b)  $\text{O}_2$  at various temperatures of 400 °C, 500 °C, 700 °C and 900 °C, respectively.  $\text{R}(1\ 1\ 0)$

stands for the Rutile peak at  $2\theta = 27.5^\circ$ , A (1 0 1) stands for the Anatase peak at  $2\theta = 25.6^\circ$ <sup>[41]</sup>

The crystalline structure will affect the refractive index. At a wavelength of 600 nm, the mean refractive index is 2.70 and 2.53 for pure rutile and anatase crystalline structure, respectively. The TiO<sub>x</sub> films after 700 °C and 900 °C contain anatase and rutile structures. The samples after annealing at 700 °C in O<sub>2</sub> and at 900 °C in forming gas show similar crystal structure and different refractive index.

### 3.3.5. Optical reflectance

The reflection of TiO<sub>x</sub> film on silicon substrate can be tuned by changing the TiO<sub>x</sub> overlay films thickness, annealing temperature and annealing gas. The variation of optical reflectance of TiO<sub>x</sub> coated silicon with wavelength for different annealing conditions is shown in Figure 3-5, including as deposited TiO<sub>x</sub> films, TiO<sub>x</sub> films annealed in forming gas and in oxygen at 400 °C.

Figure 3-5 shows that TiO<sub>x</sub> material reduces the reflectance effectively compared with bare Si. Figure 3-5 also shows the reflectance comparison between TiO<sub>x</sub> film and commonly used vacuum deposited Si<sub>3</sub>N<sub>4</sub> film as an anti-reflection layer on Si. The optical reflection after annealing TiO<sub>x</sub> films on Si at 400 °C in forming gas is very close to the Si<sub>3</sub>N<sub>4</sub>. This is considered as most optimized condition of thermal annealing for antireflection layer for silicon based devices. It indicates that such solution processable TiO<sub>x</sub> material could be used as effective anti-reflection layer for Si based solar cells and other applications.

TiO<sub>x</sub> forms uniform dense films through simple sol-gel hydrolysis process. The annealing process is also fully compatible with our Si solar cell fabrication process<sup>[46]</sup>. It

is a low cost substitution for the conventional thermal oxidation and vacuum process for  $\text{TiO}_2$  deposition. Compared with other sol-gel  $\text{TiO}_2$  material,  $\text{TiO}_x$  material could also effectively passivate the Si solar cell surface, as shown in chapter 10. Therefore  $\text{TiO}_x$  could be used for both as anti-reflection and passivation layer for Si solar cells instead of conventional high temperature thermally grown oxide and vacuum deposited  $\text{Si}_3\text{N}_4$  layers.

Figure 3-5: The measured optical reflectance from  $\text{TiO}_x$  thin films coated Si substrate for different thickness and annealing conditions, including as deposited  $\text{TiO}_x$  films before annealing,  $\text{TiO}_x$  films annealed in forming gas and in oxygen at 400 °C. The reflectance from bare silicon and commonly used  $\text{Si}_3\text{N}_4$  antireflection coating layer on Si are also shown.  $\text{Si}_3\text{N}_4$  film thickness is 70 nm<sup>[41]</sup>

### 3. 4. Conclusions

In this chapter we presented optical constant measurement results obtained by ellipsometrical method for  $\text{TiO}_x$  thin films. Three layer modeling technique was used to

determine the refractive index and extinction coefficient of the thin films. At the wavelength of 600 nm, the obtained refractive index of the as-deposited films was 1.77. This value increased to 2.57 after annealing at higher temperature, which can be explained by the development of the crystalline structure, the difference of surface morphology and the increase of the packing density of the films as indicated by AFM and XRD results. The sol-gel  $\text{TiO}_x$  thin films may be used in optical thin film applications as antireflection layer.

## Chapter 4.      **Electrical resistivity of $\text{TiO}_x$ thin films**

### **4.1. Introduction**

Various groups have studied properties of  $\text{TiO}_2$  thin films. For example, Asahi et al. calculated the electronic and optical properties of anatase  $\text{TiO}_2$  thin films <sup>[47]</sup>. Pomoni et al. reported the electrical conductivity and photoconductivity of N-doped and undoped sol–gel  $\text{TiO}_2$  thin films <sup>[48]</sup>. Sarah et al. reported electrical conductivity characteristics of  $\text{TiO}_2$  thin films annealed at various temperatures <sup>[49]</sup>. Hassan et al. studied the structural and electrical properties of sol–gel derived spun  $\text{TiO}_2$  thin films <sup>[50]</sup>.

The uniform dense  $\text{TiO}_x$  thin films are semiconducting. The electron mobility is higher than that of amorphous oxide films prepared by typical sol–gel processes <sup>[6]</sup>. It is of interest to explore the electrical properties and other application of  $\text{TiO}_x$  thin films further.

In this chapter, we studied the electrical resistivity of  $\text{TiO}_x$  thin films material. Vertical transmission line measurement method was used to extract the  $\text{TiO}_x$  bulk resistance and contact resistance. The variation of electrical resistivity at ambient and different annealing temperature was also explored. Stable electrical resistance was observed at the temperature range from 20 °C to 140 °C. The electrical resistivity decreased after high temperature annealing. The photoconductivity of  $\text{TiO}_x$  thin films was also studied.

## 4.2. Experiment

### 4.2.1. Device fabrication

The electrical resistivity measurement device structure used is shown in Figure 4-1(a). The Indium Tin Oxide (ITO) coated glass (Delta technology) was used as a substrate. The substrate was cleaned with acetone and isopropyl alcohol, and subsequently dried with nitrogen.

The  $\text{TiO}_x$  sol-gel solution in methanol was spin coated at various spin speeds onto an ITO coated glass substrate to achieve different film thicknesses. The coated sample was baked for 10 minutes at 80 °C in air, where the precursor converted to  $\text{TiO}_x$  through hydrolysis. Then a top aluminum electrode was deposited by electron beam evaporation in vacuum. The electrode was patterned through a shadow mask.

The thickness of the spin coated films was measured using a Veeco Dektak 8 stylus profilometer. Thickness was determined by the height between the top of the  $\text{TiO}_x$  film and the substrate.

To study the variation of electrical resistivity under different annealing temperatures, the heating was carried out in a rapid thermal annealing (RTA) chamber under  $\text{O}_2$  for 2 minutes at various temperatures. The gas flow for  $\text{O}_2$  was set to 100 standard cubic centimeters per minute (sccm). The  $\text{TiO}_x$  thin films, which had no heat treatment, are called as-deposited films.

When  $\text{TiO}_x$  thin films on ITO structure were annealed at temperature higher than 400 °C, the films started peeling off due to thermal expansion difference between ITO and  $\text{TiO}_x$ . Therefore, a new device structure was designed for high-temperature annealing. The  $\text{TiO}_x$  thin films were spin coated on pre-cleaned quartz substrate. The sample was

annealed in RTA chamber at different temperatures. Then two Al pads with 20  $\mu\text{m}$  separation distance were deposited above the  $\text{TiO}_x$  films, as shown in Figure 4-1 (b).

Figure 4-1: (a) ITO- $\text{TiO}_x$ -Al device structure for vertical transmission line resistance measurement (b) Device structure to process sample at high- temperature annealing studies.

#### 4.2.2 Electrical characterization

The electrical resistivity properties were measured through voltage-current measurements using a Keithley 2611 source meter.

Temperature-dependent measurements were made in a stainless steel vacuum chamber. The chamber was kept under nitrogen flow during the measurement. Samples inside the chamber were mounted onto a copper plate. The copper plate was in contact with a thermo-electric cooler that was used to heat and cool the samples. Temperature was controlled by varying the current supplied to the thermo-electric cooler. Temperature was monitored using a thermocouple inside the copper plate.

Data were taken through sequential temperature heating and cooling cycles: heating from 20  $^{\circ}\text{C}$  to 140  $^{\circ}\text{C}$ , cooling from 140  $^{\circ}\text{C}$  to 20  $^{\circ}\text{C}$ . Temperature was changed in 10  $^{\circ}\text{C}$  intervals, and data was recorded for each temperature. Temperature was held within  $\pm 1$   $^{\circ}\text{C}$  for 5 minutes during each measurement.

The TiO<sub>2</sub> material is well-known for its photoconductivity properties. The measurements were made under room light conditions.

For the photoconductivity measurement, a 400W Dymax 5000-EC UV curing flood lamp system was use to illuminate the sample with structures shown in Figure 4-1 (b). UV light (power density = 200 mW/cm<sup>2</sup>) illuminated the TiO<sub>x</sub> thin films between the Al pads. The resistance was measured with Fluke mulitimeter.

### 4.3. Results and discussion

#### 4.3.1 Electrical resistance measurement

The ITO-TiO<sub>x</sub>-Al structure is expected to behave like a diode, which generally has series resistance ( $R_S$ ) and shunt resistance ( $R_{SH}$ ) associated with them. This is indicated in the equivalent circuit diagram shown in Figure 4-2.

Figure 4-2: Schematic showing equivalent circuit for diode

A typical characteristic I-V curve of devices is shown in Figure 4-3 (a). It can be described by

$$I = I_0 [e^{q(V - IR_S)/nkT} - 1] \quad (1)$$

where  $I_0$  is the saturation current and  $n$  is the diode ideality factor. In the high current region, it can be written as <sup>[51]</sup>

$$I \frac{dV}{dI} = R_s I + \frac{nkT}{q} \quad (2)$$

Therefore,  $I(dV/dI)$  is linearly dependent on  $I$  with a slope equal to  $R_s$  in the high-current region. The series resistance can be extracted from the slope by a linear fit in the high-current region.  $I(dV/dI)$ - $I$  characteristic curve of a diode is shown in Figure 4-3 (b).

(a)

(b)

Figure 4-3: (a) Typical I-V curve for ITO-TiO<sub>x</sub>-Al structure, (b)  $I(dV/dI)$ -I characteristic curve of the ITO-TiO<sub>x</sub>-Al structure

Major contributors to the total series resistance are contact resistance between the ITO electrode and the TiO<sub>x</sub> thin films, the bulk resistance of the TiO<sub>x</sub>, contact resistance between the TiO<sub>x</sub> thin films and Al electrode, and the bulk resistance of the Al contact. Al resistance is negligible because of the much lower resistivity of Al with respect to that of the TiO<sub>x</sub> material. To extract the TiO<sub>x</sub> films bulk resistance and contact resistance from total series resistance, we used vertical transmission line measurement model.

The transmission line measurement (TLM) method was originally proposed by Shockley<sup>[52]</sup> and offers a convenient method for determining contact resistance for planar contacts. The sheet resistance of the metallization is assumed to be zero. The total resistance  $R_{total}$  between any two contacts separated by a distance L could be measured and plotted as a function of L. The resulting equation between  $R_{total}$  and L provided an estimate of bulk resistance and contact resistance through the so-called transmission line equation

$$R_{\text{total}} = R_{\text{bulk}} + R_{\text{contact}} = \rho_{\text{bulk}} \times L + R_{\text{contact}}$$

where  $\rho_{\text{bulk}}$  is the specific resistivity of  $\text{TiO}_x$  thin films.

By fabricating devices with different  $\text{TiO}_x$  films thicknesses, the bulk resistance and contact resistance can be extracted.

Samples with different  $\text{TiO}_x$  thin films thicknesses were fabricated. Each sample had 8 individual devices. Each set of result is derived from the average of good devices on a single substrate. The  $R_{\text{total}}$  vs film thickness relation is shown in Figure 4-4.

From Figure 4-4, the total specific contact resistance of ITO- $\text{TiO}_x$ , and  $\text{TiO}_x$ -Al interface was  $30 \text{ } \Omega \text{ cm}^2$ . For thin  $\text{TiO}_x$  films, the result indicates that the contact resistance is a major contributor to the total series resistance. The bulk resistivity of  $\text{TiO}_x$  was calculated as  $1.5 \times 10^7 \text{ } \Omega \text{ cm}$  for the as-deposited films.

Figure 4-4: The variation of total resistance with  $\text{TiO}_x$  film thickness

### 4.3.2 Temperature dependence of electrical resistance

For  $\text{TiO}_2$ , band conduction is considered as the main charge transport mechanism at temperature higher than 220 K <sup>[48]</sup>. The free carriers in  $\text{TiO}_2$  are due to stoichiometric deviations. The oxygen vacancies generates energy levels below the conduction band edge. The electrical resistivity of  $\text{TiO}_x$  films may change with temperature, because the energy supplied due to the heat will affect the carriers excitation in conduction band. We studied the resistivity of ITO- $\text{TiO}_x$ -Al device structure from 20 °C to 140 °C. Figure 4-5 shows the resistance measurement results for a device with 40 nm  $\text{TiO}_x$  film thickness.

There is no obvious changes for the electrical resistance of the ITO- $\text{TiO}_x$ -Al structure from 20 °C to 140 °C. It indicates that the heating has little effect for such ITO- $\text{TiO}_x$ -Al structure.

Figure 4-5: Electrical resistance of an ITO- $\text{TiO}_x$ -Al device with 40 nm  $\text{TiO}_x$  thin films at the temperature ranging from 20 °C to 140 °C

### 4.3.3 Electrical resistivity after thermal annealing

Thermal annealing has been shown to be a critical method for tuning organic material properties. The electrical resistivity is expected to change mainly due to the nonstoichiometric films composition and oxygen deficiency. As the annealing temperature increases, more oxygen vacancies are generated resulting in a sharp decrease in resistivity. Departures from stoichiometric  $\text{TiO}_2$  will also change the resistivity dramatically, ranging from  $< 10^{10} \text{ } \Omega \text{ cm}$  for  $\text{TiO}_{2.00}$  to  $10^{-2} \text{ } \Omega \text{ cm}$  for  $\text{TiO}_{1.75}$  [53].

During the thermal annealing process, the residual organic materials were removed through oxidation and evaporation; therefore the films thickness reduced. The thickness reduced to 70 % after annealing at 300 °C for 20 minutes. The as-deposited  $\text{TiO}_x$  films are amorphous. There is a phase transition from amorphous to polycrystalline at high temperature. The anatase or rutile crystalline structure was observed after annealing at temperature higher than 500 °C. The surface morphology, which will affect the contact resistance with electrode also changed after annealing [54].

The electrical resistivity changes after different thermal annealing temperature are shown in Figure 4-6. There are variations from sample to sample after annealing. The difference is due to the different composition, crystallinity, and oxygen vacancies concentration level in the samples. The lowest resistivity of 30  $\Omega \text{ cm}$  is obtained after 700 °C annealing. The changes of chemical composition and oxygen vacancies level could be the main contributor for such large resistivity change.

Figure 4-6: Electrical resistivity of  $\text{TiO}_x$  after different annealing temperatures. Different values at same temperature stands for different samples

#### 4.3.4 Photoconductivity under UV illumination

There are photo-generated hole-electron pairs during UV illumination for typical crystalline  $\text{TiO}_2$ . Therefore the conductivity of  $\text{TiO}_2$  films changes. We studied the photoconductivity response of  $\text{TiO}_x$  sample, as shown in Figure 4-7.

The resistance of the sample reduced from  $3 \times 10^6 \, \Omega$  to  $2 \times 10^3 \, \Omega$  under UV illumination after 40 seconds. It is due to the additional photo-generated carriers. When the UV light is off, the resistance recovers to the original value due to the recombination of the photo-generated carriers after 100 seconds. This recovery process is reproducible.

The sample is on a sample holder which is heated by UV exposure in the measurement. There is no such conductivity change when the UV light is blocked from

the sample. While the sample is still being heated. It indicates the change is not dominated by heating effects.

Figure 4-7: The photoconductivity response of  $\text{TiO}_x$  sample (annealed at  $500^\circ\text{C}$ ) at room temperature in air

#### 4.4. Conclusion

In this chapter, results about the electrical resistivity of  $\text{TiO}_x$  thin films are presented. ITO- $\text{TiO}_x$ -Al device structure was fabricated to extract  $\text{TiO}_x$  bulk and contact resistance through vertical transmission line measurement model. The bulk resistivity of  $\text{TiO}_x$  film was found to be  $4.7 \times 10^7 \Omega \text{ cm}$  for the as-deposited sample. Current-voltage studies show that ITO- $\text{TiO}_x$ -Al resistance is stable within the temperature range from  $20^\circ\text{C}$  to  $140^\circ\text{C}$ . Thermal annealing increased the conductivity of the  $\text{TiO}_x$  thin films.

The resistivity of the  $\text{TiO}_x$  films reduces under UV illumination due to photo generated carriers.

## Chapter 5.      **Organic solar cells: device physics, fabrication and characterization**

### **5.1 Introduction**

Organic solar cells have the potential to develop economical technology for large-scale power generation. Organic materials could produce very thin solar cells with low specific weight. They are also mechanically flexible. Much work on designing new materials, device structures and processing techniques has been carried out to improve the power conversion efficiency of such devices. Research on organic solar cells generally focuses either on solution processable organic semiconducting molecules/polymers or on vacuum-deposited small-molecular materials. Our research focuses on the solution processable fullerene/polymer devices.

In this chapter, we will first briefly review the development history of the polymer solar cells. The operation principles and characterization of the polymer solar cells will be introduced as well as the material system. Then we will describe the device structure and fabrication process of the polymer solar cells.

### **5.2 Development of polymer solar cells**

In the 1980s the polymers (including poly (sulphur nitride) and polyacetylene) were investigated in solar cells. In 1982 Weinberger et al. <sup>[55]</sup> investigated polyacetylene as the active material in an Al/polyacetylene/graphite cell. The cell had a low open-circuit voltage of only 0.3 V and a low QE of only 0.3%. A major breakthrough came in 1986 when Tang discovered that bringing a donor and an acceptor together in one cell could

dramatically increase the power conversion efficiency to 1 % <sup>[56,57]</sup>. Tang proposed the heterojunction structure.

The first report of a conducting polymer/fullerene cell, which is one of the most used donor/acceptors in heterojunction cells, came in 1993 by Sariciftci et al. <sup>[58]</sup> The cell had a relatively high fill factor of 0.48 and a PCE of 0.04 % under monochromatic illumination. The photocurrent increased more than 20 fold when C<sub>60</sub> was added as a second layer. In 1994 Yu <sup>[59]</sup> made the first dispersed polymer heterojunction organic solar cell by spin-coating a solution of MEH-PPV and C<sub>60</sub> in a 10:1 wt-ratio on ITO coated glass. Polymer/fullerene blends have been of particular interest since then. So far, polymer solar cells based on conjugated polymers as electron-donor materials blended with [6,6]-phenyl-C<sub>71</sub>-butyric acid methyl ester (PC<sub>71</sub>BM) as an electron-acceptor material have achieved ~10.6 % efficiency using tandem structure<sup>[60]</sup>.

### 5.3 Operating principles

The process of conversion of light into electricity by an organic solar cell can be described by the following steps: (1) Light absorption, (2) Exciton diffusion, (3) Exciton dissociation, (4) Charge transport, (5) Charge collection.

#### (1) Light absorption

The photoexcitations in organic materials do not directly lead to free charge carriers but to coulombically bound electron-hole pairs, called excitons. The creation of an exciton after the absorption of a photon is the first step.

#### (2) Exciton diffusion

For efficient dissociation of excitons, strong electric fields are necessary. Such local fields can be supplied via donor/acceptor interfaces. At an interface, where abrupt changes of the potential energy occur, strong local electrical fields are possible. Excitons have to reach such an interface within its lifetime. Otherwise, excitons decay via radiative or nonradiative pathways. The exciton has a diffusion length related to the exciton lifetime and diffusion coefficient. Exciton diffusion lengths in polymers and in organic semiconductors are usually around 10-20 nm.

### (3) Exciton dissociation

The exciton diffuses inside the material to reach the donor-acceptor interface. At the donor/acceptor interface, due to the different electron affinity of two materials, the electron will be acquired by the one with higher electron affinity, which is the acceptor. Blending conjugated polymers with fullerenes is a very efficient way to break apart photo-excited excitons into free charge carriers. The photo induced charge transfer in such blends happens on a time scale much faster than other competing relaxation processes.

### (4) Charge transportation

A gradient in the chemical potentials of electrons and holes is built up in a donor-acceptor junction. It contributes to a field-induced drift of charge carriers. Asymmetrical contacts (one low work-function metal for the collection of electrons and one high work-function metal for the collection of the holes) also lead to an external field. This field will drive charge carriers to reach the electrodes.

### (5) Charge collection

As a last step, charge carriers are extracted from the device through two selective contacts. A transparent indium tin oxide (ITO) matches the highest occupied molecular orbital (HOMO) levels of most of the conjugated polymers. Al contact with a work function of around 4.3 eV matches the lowest unoccupied molecular orbital (LUMO) of acceptor PCBM (electron contact) on the other side. There is carrier recombination at the active layer/ electrode interface. Therefore, additional layer that could block certain carriers would enhance the efficiency. PEDOT: PSS layer was usually put on top of ITO layer as electron blocking layer.  $\text{TiO}_x$  layer also works as hole blocking layer.

The operation mechanism is shown in the Figure 5-1.

Figure 5-1 : Operation mechanism of polymer organic solar cells.

## 5.4 Materials

### Acceptors

$\text{C}_{60}$  has a high electron affinity. It is fairly transparent and also has fair electron conductance ( $10^{-4} \text{ Scm}^{-1}$ ). This makes fullerenes a good component in organic solar cells. The solubility of simple  $\text{C}_{60}$  is limited. Wudl et al. synthesized a soluble derivative of  $\text{C}_{60}$ ,

PC<sub>61</sub>BM (1-(3-methoxycarbonyl) propyl-1-phenyl [6, 6] C<sub>61</sub>)<sup>[61]</sup>, which has been widely used in polymer/fullerene solar cells due to its solubility. [6,6]-phenyl-C71-butyric acid methyl ester (PC<sub>71</sub>BM) has also been used recently for its higher absorption than PC<sub>61</sub>BM. In our experiment, we use PC<sub>61</sub>BM as the acceptor. The molecular structure of PC<sub>61</sub>BM is shown in Figure 5-2. The PC<sub>61</sub>BM material was purchased from NanoC Inc. It was used as purchased.

Figure 5-2: Chemical structure of PCBM

## Donors

Conjugated polymer materials have a delocalized  $\pi$  electron system. They have a high extinction coefficient ( $> 10^5 \text{ cm}^{-1}$ ), which makes it possible for sufficient light absorption with thin films ( $< 100 \text{ nm}$ ). They can be modified to have a small optical band gap, which allows them to absorb most of the solar spectrum. Some important representatives of hole conducting donor-type polymers includes (1) derivatives of phenylene vinylene backbones such as poly[2-methoxy-5-(3,7-dimethyloctyloxy)]-1,4-phenylenevinylene (MDMOPPV), (2) derivatives of thiophene chains such as poly(3-hexylthiophene) (P3HT), and poly[[9-(1-octylnonyl)-9H-carbazole-2,7-diyl]-2,5-thiophenediyl-2,1,3-

benzothiadiazole-4,7-diyl-2,5-thiophenediyl] (PCDTBT). In our experiment, we use P3HT as the donor. The molecular structure of P3HT is shown in Figure 5-3. The P3HT material was purchased from Sigma Aldrich Corp. It was used as purchased.

Figure 5-3: Chemical structure of P3HT

#### Hole transporting layer

Poly (3,4-ethylenedioxythiophene):polystyrene sulfonic acid (PEDOT:PSS) is a polymer mixture of two ionomers. It is used as a transparent, conductive polymer with high ductility in different applications. Highly conducting PEDOT: PSS was purchased from H .C. Stark with a conductivity of  $1 \times 10^{-3}$  S/cm. PEDOT: PSS with a work function of around 5.0 eV can effectively block the transportation of electrons to the ITO electrode.

Figure 5-4: Chemical structure of PEDOT: PSS

#### Electrodes

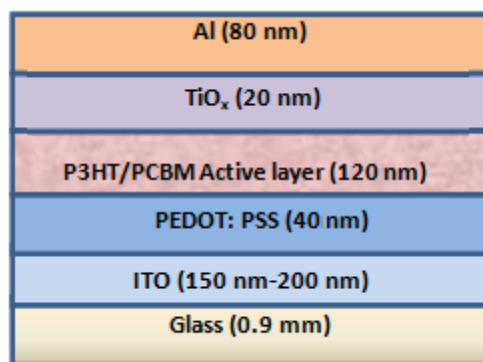

A transparent ITO, with a work function of 4.8 eV, matches the highest occupied molecular orbital (HOMO) levels of most of the conjugated polymers. Therefore it is usually used as hole collecting electrodes.

Al with a work function of around 4.3 eV matches the lowest unoccupied molecular orbital (LUMO) of acceptor PCBM on the electron collection side. Ag electrode could also be used for electron extraction contacts. The device with Ag electrode is more stable than the one with Al electrode but it is expensive.

## 5.5 Device structure

The organic solar cells in this dissertation are based on the P3HT and PCBM material system. The organic solar cell device structure and band diagram used in this study are shown in Figure 5-5.

The absorbing and charge-separating bulk-heterojunction layer is sandwiched between the ITO electrode for collecting the holes and Al electrode for collecting the electrons. The work-function difference between electrodes and different electron affinity of P3HT and PCBM provide driving force for the photogenerated carriers toward their respective electrodes. The PEDOT: PSS layer is the electron blocking layer.

Figure 5-5: Organic solar cell device structure and band diagram

Compared with normal organic solar cell device, the organic solar cell studied in this dissertation uses additional optical spacer layer. There are optical interference between the incident and back-reflected light from the metallic electrode. The intensity of the light is zero at the metallic electrode and active layer. Thus, a large fraction of the active layer is in a dead-zone at the metallic electrode side. The photo generation of carriers is significantly reduced due to lack of light absorption for thin active layer.

Introducing an optical spacer between the active layer and the Al electrode changes the spatially redistributing the light intensity inside the device, as shown in Figure 5-6.

Figure 5-6: Schematic representation of the spatial distribution of the squared optical electric field strength  $|E|^2$  inside the devices with a structure of ITO/PEDOT/active layer/Al (left) and ITO/PEDOT/active layer/optical spacer/Al (right). From J. Y. Kim <sup>[6]</sup>

The optical spacer material should satisfy optical and electrical requirements to function as a good optical spacer. The material must be non-absorbing within the solar spectrum. The material must be an electron-transport material. The conduction band edge of the material must match the  $C_{60}$  and metallic electrode.  $TiO_x$  material and zinc oxide nanoparticles have also been shown to fulfill these requirements.

$TiO_x$  layer is multi-functional layer in the organic solar cells. It is optical spacer, protection layer, hole blocking and electron transporting layer.

## 5.7 Fabrication of organic solar cells

The ITO coated glass was used as a substrate and cleaned with acetone and isopropyl alcohol and subsequently dried in nitrogen.

PEDOT: PSS was spin coated at 4000 rpm onto an ITO coated glass substrate to achieve a thickness of 40 nm. The substrate was baked for 15 minutes at 110 °C in air.

The P3HT material was purchased from Sigma Aldrich Corp and PCBM from NanoC Inc. They were dissolved in dichlorobenzene solution of 0.45 and 0.55 wt % respectively.

The solution was spin coated on an ITO coated glass substrate to produce a film of 120 nm thickness. The films were prebaked at 60 °C for 30 minutes in vacuum.

The TiO<sub>x</sub> sol-gel precursor, dissolved to 2 % by volume in methanol, was spin-coated on the top of the active layer. Subsequently, the precursor converted to TiO<sub>x</sub> by hydrolysis after 10 minutes baking in air at 90 °C. The resulting ~25 nm TiO<sub>x</sub> film was transparent and smooth. Since the TiO<sub>x</sub> layer was deposited at room temperature and treated at 90 °C, the film was amorphous.

Subsequently the device was put in vacuum chamber ( $< 10^{-6}$  torr), and 80 nm Al electrode was deposited by e-beam evaporation. The Al electrode area defined the active area of the devices.

The samples were post baked at 130 °C in air for 2 minutes before measurements of solar cell efficiency. Thermal annealing increased the crystallinity of the P3HT. The mobility of holes increased. Thermal annealing also improved the Al/active layer interaction, which helped to reduce the contact resistance.

The entire fabrication process is shown in Figure 5-7.

Figure 5-7: Fabrication process of organic solar cells in our experiment

## 5.6 Organic solar cell characterizations

Figure 5-8 (a) shows the experiment set up for characterization of the organic solar cells in this dissertation. The typical current-voltage characteristic of a solar cell under illumination is shown in Figure 5-8 (b). The parameters are described as follow.

(a)

(b)

Figure 5-8: (a) the experiment set up for characterization of the organic solar cells in this dissertation. (b) Current-voltage (I-V) curves of an organic solar cell. the maximum current density and voltage defined as  $I_{MP}$  and  $V_{MP}$ .  $V_{oc}$  is open circuit voltage,  $I_{sc}$  is short circuit current. FF is fill factor

#### Open circuit voltage ( $V_{oc}$ )

When the output contacts are isolated, the potential difference has its maximum value, the open circuit voltage  $V_{oc}$ . The operating regime of the solar cell is the range of bias, from 0 to  $V_{oc}$ , in which the cell delivers power. The open circuit voltage of this type of donor/acceptor bulk-heterojunction cell is related directly to the energy difference between the HOMO level of the donor and the LUMO level of the acceptor components. The variation of the negative electrode work function also influences the open circuit voltage. <sup>[62]</sup>

#### Short circuit current ( $I_{sc}$ )

The short circuit current corresponds to the short circuit condition when the voltage across the device equals 0.  $I_{sc}$  occurs at the beginning of the forward-bias sweep and is the maximum current value in the power quadrant. In an ideal solar cell, which has loss free contacts, this maximum current value is the total current produced in the solar cell by photon excitation. It is determined by the product of the photo generated charge carrier density and the charge carrier mobility within the active layer. The bottlenecks of  $I_{sc}$  are the absorption of the material for active layer and the mobility of charge carriers.

#### Fill factor (FF)

The Fill factor is essentially a measure of quality of the solar cell. It is calculated by comparing the maximum power to the theoretical power that would be output at both the open circuit voltage and short circuit current together. A larger fill factor is desirable, and corresponds to an I-V curve that is more square-like. Physically, fill factor is determined by charge carriers reaching the electrodes. The series resistances influence the filling factor considerably and should be minimized. Fill factor is calculated as

$$FF = \frac{I_{MP} \times V_{MP}}{I_{sc} \times V_{oc}}$$

where the maximum power output point is defined as  $P_{MAX}$ , and the maximum current density and voltage defined as  $I_{MP}$  and  $V_{MP}$ , as shown in Figure 5-5.

#### Power conversion efficiency ( $\eta$ )

Power conversion efficiency represents the ability of the cell to convert light into electricity. Efficiency is defined as the ratio of the electrical power output, compared to the incident solar power.

$$\eta = \frac{V_{oc} \times I_{sc} \times FF}{P_{in}}$$

These four quantities:  $I_{sc}$ ,  $V_{oc}$ , FF and  $\eta$  are the key performance characteristics of a solar cell. All of them should be defined for particular illumination condition. The standard test condition for solar cells is the air mass 1.5 spectrum, an incident power density of  $100 \text{ mW cm}^{-2}$ , and a temperature of  $25 \text{ }^{\circ}\text{C}$ .

## 5.7 Conclusion

In this chapter, we reviewed the development of polymer based organic solar cells. The operation principles from light absorption to free charge collection in the donor/acceptor organic solar cells were introduced. The device structure and fabrication technique used in this dissertation were described in detail.

## Chapter 6.      **Stabilization of P3HT/PCBM organic solar cells by photochemical active TiO<sub>x</sub> layer**

### **6.1. Introduction**

This chapter discusses the long-term stability of regioregular P3HT/ PC<sub>61</sub>BM based organic solar cells under ultraviolet (UV) and environmental degradation conditions.

Degradation of organic solar cells has been investigated by several groups and is considered a complex phenomenon. The degradation process involves several mechanisms, such as water absorption by a PEDOT: PSS layer, reaction of the metal/organic interface and oxidation of the organic layer <sup>[63,64, 65,66]</sup>. Lira-cantu et al <sup>[67]</sup> studied the incorporation and transport of oxygen using combination of isotopic labeling and time of flight secondary ion mass spectrometry. Norrman et al. <sup>[68]</sup> found that water effect was found to be similar the effect of molecular oxygen by studying water-induced degradation of polymer solar cells using H<sub>2</sub> <sup>18</sup>O labeling. The results on the stability for roll-to-roll process for flexible polymer solar cells have also been reported <sup>[69]</sup>. However, further studies are needed to address the issue of long-term stability of organic solar cells.

Different approaches to achieve higher stability have been considered including use of improved active materials and encapsulation schemes. Hauch et al. <sup>[70]</sup> showed that flexible P3HT: PCBM bulk heterojunction solar cell modules with more than 1 year outdoor lifetime by packaging with transparent barrier films. Lee et al. reported enhanced environmental stability for P3HT/PCBM-based organic solar cells using a TiO<sub>x</sub> layer on

top of the organic active layer <sup>[4]</sup>. Cho et al. demonstrated improvements in field effect transistor device lifetime by TiO<sub>x</sub> layer <sup>[5]</sup>. TiO<sub>x</sub> is postulated to block the passage of oxygen and humidity into the organic active layer. The mechanism proposed is based on oxygen deficiencies in the TiO<sub>x</sub> films providing adsorption sites for O<sub>2</sub> <sup>[71]</sup>.

The TiO<sub>x</sub> layer contains both Ti-OR (OR=alkoxide) functionalities and Ti-OH groups. Under UV irradiation, the Ti-OR functionalities are photo oxidized, consuming O<sub>2</sub> and generating CO<sub>2</sub>, H<sub>2</sub>O gas products and [HCOO-] and Ti-OH moieties. The role of the photoexcitation of TiO<sub>x</sub> layers was not postulated in previous works. This is another possible protection mechanism that forms the basis for TiO<sub>x</sub> films to remove oxygen when exposed to ultraviolet light.

In this chapter we studied the individual effect of oxygen and UV radiation as well as the combined effect on the degradation behavior of P3HT/PCBM organic solar cell devices. The improvements provided by placing TiO<sub>x</sub> layer between the active layer and Al electrode were examined. IR and ESR spectroscopy measurements showed that the improvements were due to photo-oxidation of the bound organic moieties causing oxygen gas scavenging.

## **6.2. Experimental**

The organic solar cell device structure was based on the P3HT and PCBM material system. The organic solar cell device structure used in this study is shown in Figure 6-1.

Figure 6-1: Organic solar cell device structure <sup>[72]</sup>

The TiO<sub>x</sub> material was described previously and was provided by Heeger's group at UC Santa Barbara. The device fabrication method and process parameters used are shown in Figure 6-2.

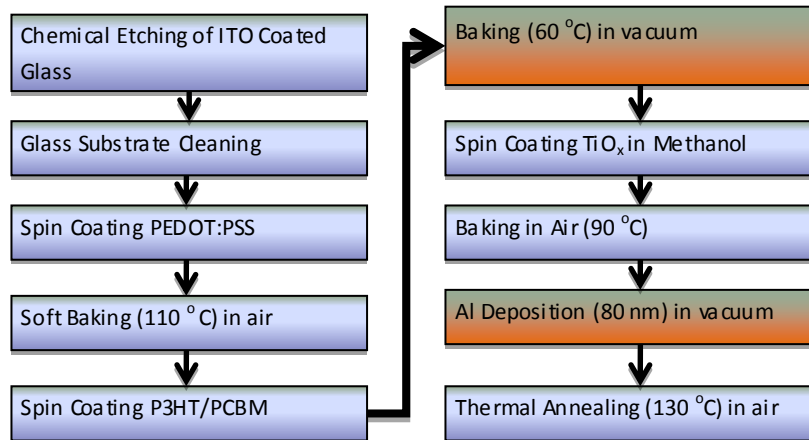

Figure 6-2: Organic solar cell fabrication process: Color coded for process in air (purple) and process in vacuum (orange) <sup>[72]</sup>

The photovoltaic cell performance was measured under AM 1.5 illumination using a calibrated solar simulator with irradiation intensity of 100 mW cm<sup>-2</sup>. The solar cell size was around 0.12 cm<sup>2</sup>. Efficiencies were 2.8% and 2% for the device with TiO<sub>x</sub> and without TiO<sub>x</sub>, respectively in air. The initial photovoltaic characterization parameters

are listed in Table 6-1. Three types of ambient conditions were used for this study that included air, oxygen and dry N<sub>2</sub> atmospheres. All experiments were carried out at room temperature.

Table 6-1: Initial photovoltaic characterization parameters

|                                 | Efficiency (%) | V <sub>oc</sub> (V) | J <sub>sc</sub> (mA/cm <sup>2</sup> ) | Fill Factor |
|---------------------------------|----------------|---------------------|---------------------------------------|-------------|
| Device without TiO <sub>x</sub> | 2              | 0.67                | 5.1                                   | 54          |
| Device with TiO <sub>x</sub>    | 2.8            | 0.64                | 7.2                                   | 57          |

All the devices without TiO<sub>x</sub> protection have been found to degrade to lower than 80% of initial efficiency during 12 hours. Therefore 12 hours time is long enough to study the degradation according to the recommended procedures for reporting organic solar cell stability <sup>[73]</sup>. Each set of data is derived from the average of 8 devices on a single substrate. We can clearly see the degradation trend and improvement that could be achieved by TiO<sub>x</sub>.

A 500 W Oriel 66033 Hg arc lamp was used in the UV light exposure studies. The radiation from the lamp was filtered with a Thorlab FGUV11S square colored glass UV filter to remove IR radiation. The lamp spectrum, compared well with solar spectrum and the transmission property of the filter is shown in Figure 6-3.

Figure 6-3 500 W Hg UV lamp spectrum, AM 1.5 solar spectrum and transmission of FGUV11S band pass filter <sup>[72]</sup>

Experiment set up for UV irradiation was shown in Figure 6-4. The lamp was held at 50 cm from the sample mounted inside the chamber and an aperture was used to limit the beam size. The solar cell samples were irradiated continuously except during few minutes of the measurement time. No heating of the samples was observed. The intensity of light incident on the sample was varied through changing the distance from light source to sample. The UV power density was measured using a Thorlab D3MM bolometer and was kept at  $10 \text{ mW cm}^{-2}$ .

Figure 6-4: Experiment set up for UV irradiation

For mechanistic studies of the behavior of  $\text{TiO}_x$  films, a  $\text{CaF}_2$  single crystal disk, 25 mm in diameter and 2 mm thick, is used as substrate.  $\text{CaF}_2$  is transparent in the visible-infrared region. The  $\text{TiO}_x$  material was dissolved to 10 % by volume in methanol, and used at room temperature to spin coat  $\sim 200$  nm films onto  $\text{CaF}_2$  disk. The disk was coated and stored in the dark in air prior to use in the experiment. The thickness of the spin coated films was measured by a Veeco Dektak 8 stylus profilometer.

Transmission IR measurements were carried out with a Bruker Tensor 27 - FTIR spectrometer with a liquid nitrogen-cooled MCT detector. The spectrometer optical path was continuously purged with dry air, scrubbed of  $\text{CO}_2$ . The instrumental resolution was  $2 \text{ cm}^{-1}$  and typical spectra involved acquisition of 128 scans. The spin-coated disk was transferred to a stainless steel ultrahigh vacuum IR cell <sup>[ 74, 75 ]</sup>. The cell contained windows for both the IR measurements as well as for irradiation of the films. Oriel

66033 Hg arc lamp was used to irradiate the sample. The radiation from the lamp was filtered with a 10 cm column of water to remove IR radiation. UV light irradiate the sample in the cell at a 45° incidence angle.

Simultaneous UV irradiation and observation of changes in the transmission IR spectrum were carried out in vacuum with  $\sim 5 \times 10^{-8}$  Torr base pressure and under an O<sub>2</sub> atmosphere at a pressure of 20 Torr. Separate IR spectra of the thin films and of the gas phase could be measured during irradiation by periodically translating the TiO<sub>x</sub> films out of the IR beam. The spectral developments in the films alone were extracted by subtracting the gas phase spectra from the spectra of the films plus gas phase .

During some measurements, a small amount of ice condensed internally on the MCT detector giving a broad ice absorption band centered near 3300 cm<sup>-1</sup>, and this band is to be disregarded. Most measurements did not involve this effect.

ESR measurements were made in a 4 mm diameter quartz ESR tube containing flakes of the fresh TiO<sub>x</sub> films. The flakes are scraped from a glass slide, where TiO<sub>x</sub> solution was spread and dried overnight in dark at room temperature in a N<sub>2</sub> environment. Exposure of the TiO<sub>x</sub> to the UV lamp was carried out in the ESR tube. A Bruker ESP 3000 spectrometer, which was automatically calibrated internally, was employed. The ESR measurements were made under N<sub>2</sub> (g) or O<sub>2</sub> (g) at 1 atm pressure.

### 6.3. Results and Discussion

#### 6.3.1. Study of solar cell degradation and improvements by $\text{TiO}_x$

Performance degradation was measured using the fabricated organic solar cell devices. Some of the degradation occurs during our fabrication process because most of the fabrication has been done in air. But the major degradation is governed by the UV and gas exposures.

At first we examined the effect of the gas environment on the degradation process. Figure 6-5 shows the change in normalized efficiency with time in dark. Significant degradation in solar cell efficiency was observed under air exposure. No degradation was noted when the experiment was repeated under nitrogen. The data also shows that significant protection is provided from air degradation by the presence of a  $\text{TiO}_x$  layer on top of the active layer.

Figure 6-5: Variation of normalized organic solar cell efficiency in air and nitrogen in dark with time <sup>[72]</sup>

Then we examined the effect of UV irradiation on the degradation process. Figure 6-6 compares the protected and unprotected solar cells performance when exposed to UV radiation in a N<sub>2</sub> atmosphere. The presence of the TiO<sub>x</sub> layer maintained the performance of the solar cells over time.

Figure 6-6: Variation of normalized organic solar cell efficiency under combined effect of UV and air exposure (UV power density = 10 mW/cm<sup>2</sup>)<sup>[72]</sup>

The combined effect of gas environment and UV light was investigated as shown in Figure 6-7. The changes in normalized solar cell efficiency as a function of ultraviolet light/air exposure time for the P3HT/PCBM organic solar cell and for a cell with the TiO<sub>x</sub> protection layer were presented. These data clearly indicate enhanced solar cell efficiency stabilization under UV irradiation in air caused by the presence of the TiO<sub>x</sub> layer. The TiO<sub>x</sub> protection is more effective in the presence of both UV and O<sub>2</sub>. The TiO<sub>x</sub> layer

when exposed to UV irradiation scavenges oxygen and consumes UV photons providing protection from UV and air exposure to organic solar cell devices.

Figure 6-7: Variation of normalized organic solar cell efficiency with UV exposure time while the sample was in a nitrogen atmosphere. (UV power density = 10 mW/cm<sup>2</sup>)<sup>[72]</sup>

The effect of UV light intensity was also examined. Figure 6-8 compares solar cell degradation under weak (10 mW/cm<sup>2</sup>) and strong (300 mW/cm<sup>2</sup>) UV irradiation in oxygen. Solar cells degrade faster when the UV flux increased 30 times. For both cases the presence of the TiO<sub>x</sub> layer enhances the stabilization over time.

Figure 6-8: Variation of normalized organic solar cell efficiency with UV exposure time while the sample was surrounded by the 1 atmosphere oxygen environment. (weak UV power density = 10 mW/cm<sup>2</sup> and strong UV power density = 300 mW/cm<sup>2</sup>)<sup>[72]</sup>

The degradation of P3HT/PCBM organic solar cells can be represented by two exponential terms that describes the fast initial decay and the long-term degradation.

$$\eta = \eta_0 [a e^{-\gamma t} + b e^{-\delta t}] \quad (6-1)$$

where  $\eta_0$  is the initial solar cell efficiency and  $a$ ,  $b$ ,  $\gamma$  and  $\delta$  are curve fitting parameters <sup>[76]</sup>.

The existence of the double exponential expression for the degradation of solar cells suggests that two major degradation processes act in parallel with time constant  $\gamma$  (hr<sup>-1</sup>) and  $\delta$  (hr<sup>-1</sup>). The time constant  $\gamma$  indicates the fast decay process and  $\delta$  is related to

slow decay. The decay process may be empirically expressed as the sum of two exponential degradation processes. But the degradation process is a complex process involving many factors. The two processes cannot be simply attributed to two separable factors such as UV degradation of the polymer and oxygen-derived degradation of the active layer in this study.

It is noted that UV degradation obtained high values of  $\gamma$  than air exposure. It suggests that faster decay may be due to UV exposure other than oxygen exposure.

We also examined the effect of the surrounding environment and UV irradiation on the various photovoltaic performance parameters such as open circuit voltage ( $V_{oc}$ ), short circuit current ( $I_{sc}$ ), fill factor (FF) and efficiency ( $\eta$ ). Figure 6-8 shows the variation of  $V_{oc}$ ,  $I_{sc}$ , and FF under UV irradiation in nitrogen. Similar results were obtained under air exposure conditions. The open circuit voltage remains essentially constant in the degradation process. It suggested that the energy level of the donor/acceptor did not change after degradation. The major loss of efficiency is due to lowering of the short circuit current and the fill factor. It suggested that the degradation affects the carrier transport of the devices.

Figure 6-9: Variation of (a) open circuit voltage( $V_{oc}$ ), (b) short circuit current ( $I_{sc}$ ) and (c) fill factor with UV exposure time when sample was surrounded by nitrogen atmosphere (UV power density =  $10 \text{ mW/cm}^2$ ) <sup>[72]</sup>

A significant change in current vs. voltage curve shape was observed for the solar cell under air degradation. There is a kink in fourth quadrant. No change was noted when the  $\text{TiO}_x$  layer was used as a protection layer as indicated in Figure 6-10. Several authors <sup>[77,78,79]</sup> have reported the observation of kink in the fourth quadrant of Figure 6-10 and have provided some explanation <sup>[80,81]</sup>. Jørgensen <sup>[66]</sup> interpreted this effect as a counter diode behavior. This is considered to be due to the formation of an interfacial layer between active organic layer and metal electrode.  $\text{TiO}_x$  layer scavenges oxygen and it

works as barrier layer to prevent the formation of the interfacial layer. Therefore there is no such kink in the device with  $\text{TiO}_x$ .

Figure 6-10: Current voltage characteristics data indicating the significant change in I-V curve shape due to air degradation<sup>[72]</sup>

Because the  $\text{TiO}_x$  absorbs UV light, this may help to protect the active layer. Therefore we studied the UV absorption effects of the protection layer. 20 nm  $\text{TiO}_x$  films were spun on quartz substrate to calculate the absorption of the  $\text{TiO}_x$  thin films. The optical path is shown in Figure 6-11.

Figure 6-11 : Optical path for absorption measurement of quartz substrate and TiO<sub>x</sub> film on quartz.

The transmission from quartz is

$$I1=I[(1-R4)- ABS_{quartz} -(1-R4-ABS_{quartz}) \times (1-R5)]$$

The transmission from TiO<sub>x</sub> on quartz is

$$I2=I \{ (1-R1)- ABS_{TiOx} -(1-R1- ABS_{TiOx}) \times (1-R2)- ABS_{quartz} -[(1-R1)- ABS_{TiOx} - (1-R1- ABS_{TiOx}) \times (1-R2)- ABS_{quartz}] \times (1-R3) \}$$

where

$$R1 = \left| \frac{1 - n_{TiO_x}}{1 + n_{TiO_x}} \right|^2 \text{ is the reflection at the Air/TiO}_x \text{ interface}$$

$$R2 = \left| \frac{n_{TiO_x} - n_{quartz}}{n_{TiO_x} + n_{quartz}} \right|^2 \text{ is the reflection at the TiO}_x \text{/Quartz interface}$$

$$R3 = \left| \frac{1 - n_{quartz}}{1 + n_{quartz}} \right|^2 \text{ is the reflection at the Quartz/Air interface}$$

$$R_4 = \left| \frac{1 - n_{\text{quartz}}}{1 + n_{\text{quartz}}} \right|^2 \text{ is the reflection at the Air/Quartz interface}$$

$$R_5 = \left| \frac{1 - n_{\text{quartz}}}{1 + n_{\text{quartz}}} \right|^2 \text{ is the reflection at the Quartz/Air interface}$$

$ABS_{\text{quartz}}$  is the absorption of the 1 mm thick quartz.  $ABS_{\text{quartz}}$  is the absorption of the 20 nm  $TiO_x$  films.

The measured absorption spectrums of quartz substrate and  $TiO_x$  film on quartz are shown in Figure 6-12.

Figure 6-12: Absorption spectrum of quartz substrate and  $TiO_x$  film on quartz

The calculated absorption of 20 nm  $TiO_x$  films is shown in Figure 6-13 (a). The corresponding absorption coefficient of  $TiO_x$  is shown in Figure 6-13 (b). The 20 nm films would absorb less than 15 % of the photons in the UV region. It may affect the UV induced degradation. But it is not the major factors.

(a)

(b)

Figure 6-13: The calculated absorption of 20 nm  $\text{TiO}_x$  films (a) absorption spectrum (b) corresponding absorption coefficient

### 6.3.2. TiO<sub>x</sub> improvement mechanism study

TiO<sub>x</sub> films contains both Ti-OR functionalities and Ti-OH groups throughout. The residual Ti-OR functionalities bound into the sol-gel films are photooxidized under UV irradiation. The process consumes O<sub>2</sub> (gas) and produces CO<sub>2</sub> (gas) and H<sub>2</sub>O (gas), as well as bound formate [HCOO-], H<sub>2</sub>O and Ti-OH moieties. The photo activation of TiO<sub>x</sub> films leads to O<sub>2</sub> scavenging which removes absorbed oxygen that would degrade the solar cell devices. Thus, TiO<sub>x</sub> film protects the underlying surface from oxygen gas.

Figure 6-14 shows the infrared spectral measurements of the production of CO<sub>2</sub> (gas) and H<sub>2</sub>O (gas) during UV photoactivation of the TiO<sub>x</sub> film at room temperature during which the <sup>16</sup>O<sub>2</sub> pressure was 20 Torr. Broadened CO<sub>2</sub> vibration-rotation bands, centered at 2349 cm<sup>-1</sup>, is observed (asymmetric stretching mode) over the 32 hour irradiation period. It indicates that CO<sub>2</sub> is monotonically generated. Two spectral regions for H<sub>2</sub>O (gas) are also observed. One is centered near 3700 cm<sup>-1</sup> (stretching mode) and another is near 1600 cm<sup>-1</sup> (bending mode). It indicates the monotonically develop absorbance of H<sub>2</sub>O (gas). The infrared peaks positions were identified in accordance with the reported results as described in reference [82].

Figure 6-14: Gas phase photooxidation products from  $\text{TiO}_x$  films containing alkoxide functionalities.  $\text{CO}_2$  (gas) and  $\text{H}_2\text{O}$  (gas) are observed. The slow formation of ice on the IR detector is an artifact to be disregarded. The spectrum through the gas phase at each time was ratioed by the spectrum taken before UV irradiation <sup>[72]</sup>

Figure 6-15 shows the infrared spectral developments when the  $\text{TiO}_x$  films are irradiated during an 8 hours at room temperature under  $^{16}\text{O}_2$  (gas) at 20 Torr pressure. Characteristic of the alkoxide functional groups remaining in the  $\text{TiO}_x$  films is observed in the (C-H) stretching region. It may be seen that considerable loss of absorbance occurs at  $2926\text{ cm}^{-1}$  and  $2853\text{ cm}^{-1}$  when photooxidation of the alkoxide takes place. The modes at the frequencies above the (C-H) stretching region are due to surface hydroxyl (Ti-OH) groups and adsorbed water in the  $\text{TiO}_x$  films and their absorbances are observed to grow

during the photooxidation process. A very weak  $\text{C}\equiv\text{N}$  stretching mode [ $\nu(\text{C}\equiv\text{N})$ ] at  $2201\text{ cm}^{-1}$  is observed. It is due to the photo-oxidation of residual ethanolamine from the  $\text{TiO}_x$  precursor preparation.

Shifting to a congested spectral region below  $1750\text{ cm}^{-1}$ , where asymmetric and symmetric OCO stretching modes develop for  $\text{HCOO}^-$  species, subtle increases occur in absorbance at  $1567\text{ cm}^{-1}$  and  $1359\text{ cm}^{-1}$ , as marked. The vibrational frequencies observed are close to those found for formate species [ $\text{HCOO}^-$ ] on  $\text{TiO}_2$  in published reports [83,84,85,86].

Figure 6-15: Surface species consumption and formation during photooxidation of  $\text{TiO}_x$  films containing alkoxide functionalities. The consumption of the alkoxide functionality is accompanied by the formation of carboxylate and hydroxyl surface-bound species, as well as nitrile moieties from the oxidation of ethanolamine [72]

Figure 6-16 shows ESR spectra of  $\text{TiO}_x$  material recorded after exposure to UV irradiation for 15 minutes in 1 atm of  $\text{O}_2$  (g) at 295 room temperature. Three strong ESR features are observed at  $g = 2.030$ ,  $g = 2.006$  and  $g = 2.001$ . The three ESR transitions are assigned to adsorbed  $\text{O}_2^-$  [87,88]. The trapping of the electron by  $\text{O}_2$  stabilizes the hole produced in the  $\text{TiO}_x$  films.

Figure 6-16: ESR spectrum showing the effect of UV light on  $\text{TiO}_x$  under  $\text{O}_2$  at 1 atm. (a) after UV irradiation, 15 minutes; (b) before irradiation<sup>[72]</sup>.

There is no production of  $O_2^-$  by UV irradiation for 60 minutes with the  $TiO_x$  sample under 1 atm of  $N_2$ , as shown in Figure 6-17. Compared to the results found for UV irradiation in  $O_2$  in Figure 6-16, the results clearly indicate that the photo-formation of trapped electrons is directly associated with the formation of adsorbed  $O_2^-$ .  $O_2$  (g) is required for photochemical formation of  $O_2^-$  species in  $TiO_x$ .

Figure 6-17: ESR spectrum of the effect of UV light on  $TiO_x$  under  $N_2$  at 1 atm. (a) after UV irradiation, 60 minutes; (b) before irradiation. The results, compared to Figure 6-16, show that  $O_2^-$  species require  $O_2(g)$  for photochemical formation on  $TiO_x$ <sup>[72]</sup>

The ability of TiO<sub>x</sub> films, containing internally chemically-bound alkoxide groups, to photochemically consume oxygen is not surprising based on the wide utility of TiO<sub>2</sub> for the photooxidation of *ex situ* organic and inorganic matter [89,90,91]. The TiO<sub>x</sub> films carries its own sacrificial organic reactant while also containing ultraviolet light absorbing  $\cdots\text{Ti-O-Ti}\cdots$  structures throughout the films, capable of making electron-hole pairs which then promote redox processes. It is also observed that the presence of adsorbed O<sub>2</sub> facilitates electron-hole pair separation by acting as an electron acceptor.

### 6.3.3 Protection capacity calculation

Estimation of the capacity of the bound –OR a group within the TiO<sub>x</sub> films for reaction with oxygen gas is calculated here:

A 20 nm film of TiO<sub>x</sub> contains about  $3 \times 10^{16}$  TiO<sub>x</sub> units per cm<sup>2</sup>. There is about 10 - 50 mole % of –OCH<sub>3</sub> groups exist in the films. The capacity for photo-oxidative reaction with O<sub>2</sub> is of order of  $3 \times 10^{15} - 1.5 \times 10^{16}$  O<sub>2</sub> molecules cm<sup>-2</sup>. There is a volume of about  $1 \times 10^{-5}$  cm<sup>3</sup> for the 120 nm active layer with 1 cm<sup>2</sup> surface area. It is reported that the critical doping level for electron traps generated by O<sub>2</sub> for P3HT is between  $10^{16}$  cm<sup>-3</sup> [92] and  $10^{17}$  cm<sup>-3</sup> [93]. It is about  $10^{11} - 10^{12}$  per cm<sup>2</sup> of active area. Thus, the TiO<sub>x</sub> protective films have a capacity of the order of  $10^4$  to  $10^5$  times than the quantity of O<sub>2</sub> which is needed to seriously influence the active layer performance.

As stated in the introduction chapter, oxygen deficiencies in the TiO<sub>x</sub> films also provide adsorption sites for O<sub>2</sub>. The TiO<sub>x</sub> layer also acts as a diffusion barrier for oxygen which slows down the oxygen travel. The combination of these three mechanisms provides of the TiO<sub>x</sub> protection for organic solar cells. Table 6-2 shows comparison of

efficiency degradation with time for the device with  $\text{TiO}_x$  protection and device without  $\text{TiO}_x$ . The efficiency of device without  $\text{TiO}_x$  protection degraded from 1.92% to 0.09% after 1 week while the efficiency of device with  $\text{TiO}_x$  protection degraded from 2.39% to 1.91%. The comparison indicates that the protection of  $\text{TiO}_x$  lasts more than one hundred hours.

Table 6-2: Comparison of efficiency degradation with time for the device with  $\text{TiO}_x$  protection and device without  $\text{TiO}_x$

|                               | As prepared | 1 week |
|-------------------------------|-------------|--------|
| Device without $\text{TiO}_x$ | 1.92%       | 0.09%  |
| Device with $\text{TiO}_x$    | 2.39%       | 1.91%  |

#### 6.4. Conclusions

From this study on stabilization of P3HT/PCBM based organic solar cells with a  $\text{TiO}_x$  layer, we can draw following conclusions:

(1) The P3HT/PCBM organic solar cell efficiency decreases with increase in air exposure time. No change was noted under nitrogen. Thin films of  $\text{TiO}_x$  on top of the active layer provided significant protection from air degradation.

(2) The cell performance decreases with increasing UV exposure under nitrogen. Thin films of  $\text{TiO}_x$  layer on top of the active layer provided significant protection from UV exposure.

(3) A higher decrease rate in cell efficiency was noted when exposed to the combined effect of UV and oxygen, as compared to the individual effects. The  $\text{TiO}_x$  protection is more effective in the presence of both UV and  $\text{O}_2$ . The  $\text{TiO}_x$  layer scavenges oxygen and consumes UV photons providing protection from UV and air exposure to organic solar cell devices.

From the  $\text{TiO}_x$  mechanism study, we have discovered the following properties of  $\text{TiO}_x$  sol-gel films which act as photochemically-activated oxygen scavengers:

(1) UV irradiation of  $\text{TiO}_x$  films containing alkoxide groups remaining from the sol-gel synthesis leads to the photochemical oxidation of these organic groups. This process removes  $\text{O}_2(\text{gas})$  and forms  $\text{H}_2\text{O}(\text{gas})$ ,  $\text{CO}_2(\text{gas})$ , chemically-bound formate  $[\text{HCOO-}]$ ,  $\text{H}_2\text{O}(\text{ad})$  and  $\text{Ti-OH}$  oxidation products. It is the photochemical removal of  $\text{O}_2$  by  $\text{TiO}_x$  films that is postulated to lead to passivation of organic photocells from oxygen induced degradation.

(2).  $\text{O}_2^-$  species are observed to form where  $\text{TiO}_x$  films are irradiated in  $\text{O}_2(\text{g})$  at room temperature. In the absence of  $\text{O}_2(\text{g})$ , these species are not detected by ESR upon UV irradiation.

## Chapter 7.      **Laser beam induced current mapping study on organic solar cell with TiO<sub>x</sub> protection layer**

### 7.1 **Introduction**

Traditional electrical characterization of solar cells, which involves extracting the photovoltaic parameters such as open circuit voltage ( $V_{oc}$ ), short circuit current ( $I_{sc}$ ), fill factor and efficiency ( $\eta$ ) by performing I-V scan, is useful for determining the overall parameters of solar cells. But it does not show the local information of the cells. The inhomogeneity of the local photocurrent has been reported in organic solar cells upon degradation for P3HT/PCBM cells <sup>[94]</sup>. T. Jeranko et al. conclude that degradation mechanisms appear to have a morphological component in MDMO-PPV/PCBM composite polymer solar cells <sup>[95]</sup>. This type of measurement is complemented with laser beam induced current (LBIC) mapping of the devices to gain further insight into the local degradation of the cells.

LBIC imaging is a non-destructive characterization technique suitable for the investigation of large two-dimensional arrays of semiconductor devices. It is a very useful tool in determining the spatial variability of properties such as power conversion efficiency and has been used to study defects <sup>[96]</sup> and crystalline effect <sup>[97]</sup> for organic solar cells.

In this chapter, we will use LBIC measurements to explore local photocurrent distribution in the cells with and without TiO<sub>x</sub> protection layer and analyze the obtained degradation patterns.

## 7.2 Experiment

### 7.2.1 Organic solar cell fabrication

The organic solar cells were fabricated according to previous chapters with an effective active area of  $0.1 \text{ cm}^2$ . The photovoltaic parameters of the device with and without  $\text{TiO}_x$  layer are shown in Table 7-1.

Table 7-1: The photovoltaic parameters of the device for LBIC study

| Device              | Efficiency | $V_{oc}$ (V) | $J_{sc}$ ( $\text{mA}/\text{cm}^2$ ) | Fill Factor (%) |
|---------------------|------------|--------------|--------------------------------------|-----------------|
| No $\text{TiO}_x$   | 1.96       | 0.696        | 6.1                                  | 46.1            |
| With $\text{TiO}_x$ | 2.36       | 0.708        | 7.17                                 | 46.5            |

### 7.2.3 LBIC set up

A schematic of LBIC set up is shown in Figure 7-1.

Figure 7-1 : A schematic of LBIC set up

The the P3HT/PCBM blend (45% : 55%) absorption peak is around at 500~550 nm<sup>[98]</sup>, a green diode laser (532 nm) following Gaussian power distribution was chosen as light source. The laser beam was focused on the cell in a small spot and the resulting photocurrent was measured point by point. The intensity, adjustable by polarizer, of the focused laser beam was 50 mW/cm<sup>2</sup> as measured by power detector.

The solar cells were mounted on a scan stage which allows movement of the sample in the x and y directions. The spatially resolved photocurrent images were obtained.

The image resolution depends on the size of the laser spot and scanning process. The limiting factor is the microscope lenses through which laser beam was focused. The laser beam was focused to 25  $\mu\text{m}$ , which was measured by laser beam profiler (BP109-VIS, Thorlab).

A custom written computer program by Labview<sup>[99]</sup> was used to scan the solar cell devices in a pattern of 25  $\mu\text{m}$  increment in the X and the Y directions, logging the increment coordinates and measured current. The current induced by the laser beam from the device was measured using a computer-interfaced source measure unit (Keithley 2600 instrument). The results were then converted into 2-D maps by Origin lab V7.5.

## 7.3 Results and discussion

### 7.3.1 Efficiency patterns

The current mapping for as prepared device with  $\text{TiO}_x$  layer is shown in Figure 7-2(a). Bright red represents the highest absolute current extracted while black represents the lowest current.

Devices with high initial efficiency usually show good uniformity. Less uniformity is indicated by larger LBIC variations in poor performing cells, as shown in Figure 7-2 (b).

(a)

(b)

Figure 7-2: LBIC mapping of as prepared devices (a) with  $\text{TiO}_x$  (device efficiency  $\eta=2.4$ )  
(b) without  $\text{TiO}_x$  (device efficiency  $\eta=1.6$ )

### 7.3.2 Island formation

Upon degradation, islands of lower photocurrent occur. Figure 7-3 (a) shows defects regions. The islands in rectangular area are due to the bubbles in the Al contact, which form during the 130 °C annealing process as the remaining solvent, such as chlorobenzene, evaporates. The circular regions are most likely due to the non-uniformity in coating.

Figure 7-3 (b) shows defect regions appearing after degradation. It is probably due to the oxidation due to the microscopic pinholes in the Al electrode surface from ambient air. It has been reported that oxygen diffuses through pinholes in the aluminum electrode <sup>[100]</sup>. The sizes of the pin holes are up to a few micrometers in diameter and

their depth may be up to tens of nanometers. The aluminum electrode experiences oxidation/degradation in both the lateral and vertical plane.

(a) as prepared device

(b) Degraded device

Figure 7-3: Degradation pattern of OSC device with  $\text{TiO}_x$  layer (a) as prepared device (b) device degraded in dark for 1 week.

### 7.3.3 Comparison of devices with/without $\text{TiO}_x$ protection

Figure 7-4 shows the degradation of the devices without  $\text{TiO}_x$  protection for 10 days. The LBIC mapping of as prepared cells without the  $\text{TiO}_x$  layer is shown in Figure 7-4(a). Figure 7-4(b), 7-4(c) and 7-4(d) show the device at various stages of degradation. As degradation occurred, the active area had apparently shrunk and more and more spots of low-photocurrent appeared.

(a) as prepared device

(b) 1 day

(c) 3 days

(d) 10 days

Figure 7-4: The mapping of degradation process for device without  $\text{TiO}_x$  protection (a) as prepared device (b) degradation after 1 day (c) degradation after 3 days (d) degradation after 10 days

For the cells with  $\text{TiO}_x$  protection layer, low photocurrent points were also observed (see Figure 7-5). But the shrinkage of the active area was not observed, and degradation spots were much smaller in comparison with the cell without the  $\text{TiO}_x$  layer.

It is also confirmed by full devices scanning. Figure 7-6 shows the current mapping of degradation of full device without  $\text{TiO}_x$  protection layer. Compared with device with  $\text{TiO}_x$  layer, as shown in Figure 7-3, the device without  $\text{TiO}_x$  layer degraded less in the device central region.

It has been reported that the shrinkage of the active region could be due to water in ambient air and oxidation of the contact<sup>[94]</sup>. PEDOT:PSS absorbs water from ambient air and accelerates the oxidation of Al, resulting a reduction in the efficiency. The TiO<sub>x</sub> layer absorbs water and oxygen, therefore it prevents degradation from the edge area.

(a) as prepared device

(b) 1 day

(c) 5 days

(d) 10 days

Figure 7-5: The current mapping of degradation process for device with  $\text{TiO}_x$  protection

 degradation after 10 days

(a)

(b)

Figure 7-6: The current mapping of degradation without  $\text{TiO}_x$  protection (a) as prepared device (b) device after 1 week.

## 7.4 Conclusion

2D images of the local photocurrent in cells with and without  $\text{TiO}_x$  protection layers were obtained by LBIC measurements. Degradation spots were observed in devices. The enhancement of the degradation spots were observed with time in all the cells. However, the shrinkage of the active area from the edge was observed only in the OSC without  $\text{TiO}_x$ . The results show that the introduction of the  $\text{TiO}_x$  layer could effectively absorb water/oxygen from ambient air and protect the cells at the edge and top.

## Chapter 8. A study on doping of $\text{TiO}_x$ thin films

### 8.1 Introduction

#### Current problem

The enhancement of efficiency and long term stability of organic solar cells by  $\text{TiO}_x$  has been demonstrated in our previous study. However, the electrical resistance of such films is still high and may affect the conversion efficiency. The series resistance of the organic solar cell changes due to insertion of this additional  $\text{TiO}_x$  layer.<sup>[101]</sup> In our experiment, we explored method to reduce the series resistance of OSC after adding  $\text{TiO}_x$  layer. It has been demonstrated that the properties of metal oxides can be enhanced and tuned through the addition of various dopants and processing methods<sup>[103]</sup>. We have investigated the doping of  $\text{TiO}_x$  to improve performance of OSC.

#### Choice of dopant

The dopant must be compatible with sol-gel process employed in synthesis of the  $\text{TiO}_x$  precursor. The doped  $\text{TiO}_x$  should be prepared by wet chemical synthesis and should be highly soluble in methanol, which is used to dilute  $\text{TiO}_x$  precursor.

#### Cesium and Fe dopant

Cesium carbonate ( $\text{Cs}_2\text{CO}_3$ ) has been widely incorporated for electron injection and transport enhancement in organic devices<sup>[102,103]</sup>, usually as an n-type dopant in organic electron-transport films. Doped nanocrystalline  $\text{TiO}_2$  prepared by adding a  $\text{Cs}_2\text{CO}_3$  has been reported<sup>[104]</sup>. The interfacial  $\text{TiO}_2$ : Cs layer facilitates electron transport from the active layer to the cathode. Therefore the series resistance can be expected to decrease.

Another way to modify the electrical properties of is to introduce defects into the  $\text{TiO}_2$  lattice by doping with transition metals, e.g. Fe(III). It is generally accepted that Fe(III) centers form shallow charge trapping sites with the  $\text{TiO}_2$  matrix as well as on the particle surface through the replacement of Ti(IV) by Fe(III) <sup>[105]</sup>, as shown in Figure 8-1. The trapping site will reduce the e - h recombination rate as electron transfers from the trapping site to molecular oxygen more rapidly than the undoped  $\text{TiO}_2$ .

Figure 8-1: Energy level of  $\text{TiO}_2$  changes after Fe doping, From C.-Y. Wang et. al 2003

The sol-gel method has been widely used for preparation of Fe-doped  $\text{TiO}_2$  from  $\text{TiCl}_4$  or titania alkoxide ( $\text{TiO}_x$ ) and an iron precursor like  $\text{FeCl}_3$ ,  $\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  or Fe(III)-acetylacetonate <sup>[106]</sup>. Since Fe (III)-acetylacetonate is soluble in methanol, it was chosen as Fe dopant.

We have explored the application of novel  $\text{TiO}_x$  thin films doped with  $\text{Cs}_2\text{CO}_3$  for OSC applications. We also noted the effect of doped  $\text{TiO}_x$  films on OSC device parameters like efficiency, open circuit voltage, short circuit current and fill factor.

## 8.2 Experiment

### 8.2.1 TiO<sub>x</sub> precursor doping

The TiO<sub>x</sub> precursor was synthesized according to previous chapter.

Because, as previously noted, Cs<sub>2</sub>CO<sub>3</sub> has a high solubility in methanol. Thus, the doping of Cs<sub>2</sub>CO<sub>3</sub> is compatible with the solution processing of TiO<sub>x</sub> sol gel. Cs<sub>2</sub>CO<sub>3</sub> was dissolved in methanol for the purpose of this experiment. TiO<sub>x</sub> precursor was diluted to 1 % before mixing. Then the solutions of Cs<sub>2</sub>CO<sub>3</sub> of different concentration were mixed with TiO<sub>x</sub> sol-gel and mixing ratio was 1:1 by volume to dope TiO<sub>x</sub> precursor.

Fe (III)-acetyloacetate also has a high solubility in methanol. In this experiment, Fe (III)-acetyloacetate was dissolved in methanol. Then the solutions of Fe (III)-acetyloacetate of different concentration were mixed with TiO<sub>x</sub> sol-gel at the ratio of 1:1 by volume to dope TiO<sub>x</sub> precursor.

The solution of Fe (III)-acetyloacetate is yellowish at low concentration (less than 1 %) and becomes reddish with the increasing Fe concentration. The Cs<sub>2</sub>CO<sub>3</sub> solution is transparent.

### 8.2.2 Resistivity measurement

The resistivity of the TiO<sub>x</sub> and doped TiO<sub>x</sub> was measured by the structure shown in Figure 8-2. Two Al electrodes, 1 cm in length, were deposited on the top of insulating glass material by e-beam evaporation. The distance between two electrodes was 150 μm. The thickness of the electrode was 100 nm. TiO<sub>x</sub> precursor was spin coated on the glass with Al electrode to a thickness of more than 100 nm, measured using a Veeco Dektak 8

stylus profilometer. Electrical measurements were made using HP 4145B semiconductor parameter analyzer.

Figure 8-2:  $\text{TiO}_x$  between to electrodes to measure the resistivity

### 8.2.3 Organic solar cell fabrication

The fabrication of organic solar cell follows the recipe of previous chapters. Doped  $\text{TiO}_x$  precursor is made by mixing  $\text{TiO}_x$  precursor and the doped methanol solution. After coating of the active PCBM/P3HT layer, the doped precursor was spin-coated on the top of active layer. Doping did not change the wetting property of the  $\text{TiO}_x$  precursor. The coated device was soft baked on the 80 °C hot plate in air. Then Al electrodes were deposited using e-beam and the device was thermally annealed in vacuum for 2 minutes at 130 °C.

## 8.3 Results and discussion

### 8.3.1 Fe doped $\text{TiO}_x$

The photovoltaic parameters of devices of different doping levels are listed in Table 8-1. The  $\text{TiO}_x$  thin film thickness was optimized to obtain the highest efficiency. The data in the table is the average of optimized devices on one substrate.

The short circuit current is higher for the device with doped and undoped  $\text{TiO}_x$  due to enhancement of light absorption generated by the spacer layer. The device with doped  $\text{TiO}_x$  shows 5 % improvement than the devices with undoped  $\text{TiO}_x$ . Fill factor increases to around 8 % while the series resistance reduces by 9 %. Because Fe doping reduces the resistivity of  $\text{TiO}_x$ , which facilitates the carrier transportation, therefore the current and fill factor improved upon doping. Fe doping also affects the energy level alignment because the open circuit voltage reduces compared with undoped  $\text{TiO}_x$ . The overall efficiency is 11 % higher for doped  $\text{TiO}_x$ .

Table 8-1 The photovoltaic parameters of devices with Fe doped  $\text{TiO}_x$

| Samples                       | $V_{oc}$ (V) | $J_{sc}$ ( $\text{mA}/\text{cm}^2$ ) | Efficiency (%) | FF (%) | $R_s$ ( $\text{ohm} \cdot \text{cm}^2$ ) |
|-------------------------------|--------------|--------------------------------------|----------------|--------|--|
| Reference                     | 0.696        | 5.24                                 | 1.82           | 49.8   | 29                                       |
| with $\text{TiO}_x$           | 0.708        | 7.17                                 | 2.36           | 46.5   | 24                                       |
| $\text{TiO}_x$ with 1 % $F_e$ | 0.687        | 7.54                                 | 2.62           | 50.6   | 22                                       |

Figure 8-3 shows the I-V curve of device with  $\text{TiO}_x$  of 1 % Fe doping. It is clear that Fe doping changes the short circuit current and open circuit voltage of the devices.

Figure 8-3 : I-V curve of device with 1 % Fe doped  $\text{TiO}_x$  under 1 sun light illumination. Ref stands for devices without  $\text{TiO}_x$ ,  $\text{TiO}_x$  and doped  $\text{TiO}_x$  stand for devices with original  $\text{TiO}_x$  and doped  $\text{TiO}_x$  material, respectively

The resistivity of Fe doped  $\text{TiO}_x$  material is shown in Figure 8-4. The resistivity value is the average of 3 samples. It is observed that the resistivity of  $\text{TiO}_x$  material starts to reduce with increase of Fe doping. The resistivity decreases about 30 % with 1 % Fe doping. But the resistivity increases with more Fe doping. Therefore we can conclude that Fe doping slightly reduces the resistivity of  $\text{TiO}_x$  material.

Figure 8-4: The resistivity of  $\text{TiO}_x$  material upon doping with Fe of different concentration

### 8.3.2 Cs doped TiO<sub>x</sub>

Figure 8-5 shows the I-V curve of device with TiO<sub>x</sub> of different Cs doping level in dark. It shows that doping with Cs reduces the resistance in the 0~1 V region. But the reverse current also increased for highly doped TiO<sub>x</sub>.

Figure 8-5 : I-V curve of device with 1% TiO<sub>x</sub> of different Cs doping level.

The photovoltaic parameters of devices of different doping levels are listed in Table 8-2. The short circuit current is higher due to enhancement of light absorption generated by the space layer. The open circuit voltage is lower due to the possibility of energy level alignment modified by Cs doping. The overall performance for doped TiO<sub>x</sub> material does not show significant improvement compared with undoped TiO<sub>x</sub>. Therefore Cs doping does not improve the TiO<sub>x</sub> for organic solar cells.

Table 8-2: Photovoltaic parameters of devices of different doping levels at various TiO<sub>x</sub> concentration levels

| Samples   | V <sub>oc</sub> (V) | J <sub>sc</sub> (mA/cm <sup>2</sup> ) | Efficiency (%) | FF (%) |
|---|---------------------|---------------------------------------|----------------|--------|
| References sample   | 0.7                 | 2.15                                  | 0.51           | 34     |
| TiO <sub>x</sub> only                                     | 0.48                | 3.34                                  | 0.61           | 38     |
| TiO <sub>x</sub> : 0.2 % Cs <sub>2</sub> CO <sub>3</sub>  | 0.51                | 3.04                                  | 0.6            | 39     |
| TiO <sub>x</sub> : 0.05 % Cs <sub>2</sub> CO <sub>3</sub> | 0.51                | 1.53                                  | 0.26           | 33     |
| TiO <sub>x</sub> : 1 % Cs <sub>2</sub> CO <sub>3</sub>    | 0.14                | 0.73                                  | 0.03           | 26     |

#### 8.4 Conclusion

In this chapter, we investigated the effect of Cs and Fe doping on the TiO<sub>x</sub> properties. Device with Cs doped TiO<sub>x</sub> does not show improvement on the photovoltaic performance whereas Fe does demonstrated doping improved series resistance, fill factor and short circuit current; therefore the power conversation efficiency improved by 11 %.

## Chapter 9. **TiO<sub>x</sub> thin films as surface passivation and anti-reflection coating for silicon solar cells**

### **9.1 Introduction**

In this chapter, we first study the optical properties of TiO<sub>x</sub> thin films on polished and chemically textured silicon surfaces. We then evaluate the properties of silicon solar cells with TiO<sub>x</sub> thin films using the conventional solar cell fabrication process. We then study the surface passivation effect of these films by near-surface lifetime measurement technique <sup>[107]</sup>.

### **9.2 Experiment**

The TiO<sub>x</sub> solution was spin-coated on p- and n-type Cz Si (100) with  $\rho = 1 \ \Omega \text{ cm}$  and the bulk minority carrier lifetime  $> 500 \ \mu\text{s}$ . Chemically textured silicon surfaces were prepared using tetramethylammonium hydroxide (TMAH) solution <sup>[108]</sup>. Optical reflection measurements were carried out using a Filmetrics thickness measurement tool. Integrated reflection measurements were made by a spectrophotometer attached with an integrating sphere with incident angle of  $35^\circ$ . The  $80^\circ\text{C}$  annealing process was performed on hot plate in air. The  $400^\circ\text{C}$  annealing process was performed in the RTA system using forming gas for 20 minutes.

Silicon solar cells were prepared on polished and chemically textured surfaces as shown in Figure 9-1<sup>[46]</sup>.

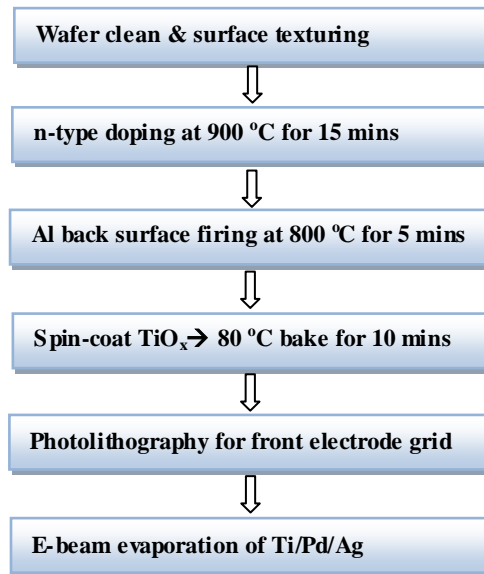

Figure 9-1: Process flow for fabricating silicon solar cells <sup>[46]</sup>

I–V measurements are carried out using solar simulator. Quantum efficiency is measured using an IV setup and a tungsten halogen lamp. A 270M Jobin Yvon monochromator was used to get individual wavelengths.

Near-surface lifetime was measured by a technique based on photoconductive decay (PCD) method. Figure 9-2 shows the experimental set-up for measuring the surface lifetime of TiO<sub>x</sub> thin films spin-coated on Si substrate. The TiO<sub>x</sub> thin films were then patterned using photo lithography. Two windows were opened up in the TiO<sub>x</sub> thin films in order to make electrical contact with the wafer. The focused laser beam is illuminated between the contacts. The decay across the resistor is monitored on an oscilloscope.

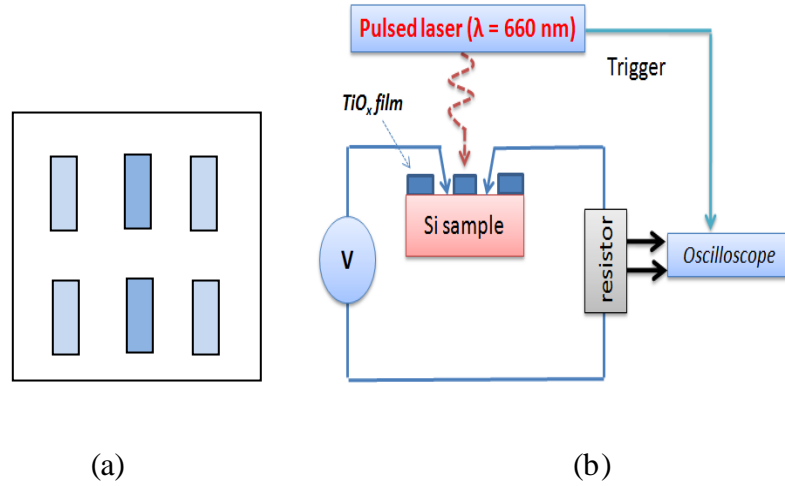

Figure 9-2: (a) Pattern and (b) experimental set-up for surface lifetime measurement <sup>[46]</sup>

## 9.3 Results and discussion

### 9.3.1 Optical measurement

In chapter 3, we demonstrated that the Si reflection values from  $TiO_x$  coating are comparable to the values of conventional silicon nitride. Figure 9-3 shows that  $TiO_x$  films are able to reduce the reflection to about 5 % for chemically textured silicon surfaces.

Figure 9-3: Total integrated reflection for a chemically textured surface with and without  $\text{TiO}_x$  films <sup>[46]</sup>

### 9.3.2 Photovoltaic device characterization

Si solar cell devices were fabricated on a polished p-type substrate with a phosphorus emitter. The device structures for Si solar cells with  $\text{TiO}_x$  layer only and for solar cells with  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  layers are shown in Figure 9-4. The obtained photovoltaic performance parameters are listed in Table 9-1. It can be seen that the performance of device with  $\text{TiO}_x$  as anti-reflection and passivation layer are comparable to the one using  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  layers.

Figure 9-4: Device structures for Si solar cells with (a)  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  layer and (b)  $\text{TiO}_x$  layer

Table 9-1: Device performance for the Si solar cells with  $\text{TiO}_x$  layer and  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  layers

|                                      | Efficiency (%) | $V_{oc}$ (mV) | $J_{sc}$ (mA/cm <sup>2</sup> ) | Fill Factor |

The I-V characteristic curve and external quantum efficiency of the solar cells with  $\text{TiO}_x$  coatings are shown in Figure 9-5.

Figure 9-5: (a) Dark and light I-V curves and (b) external quantum efficiency and reflection curves for Si solar cells with  $\text{TiO}_x$  thin films as the surface passivation and anti-reflection coating<sup>[46]</sup>

The results of the devices with chemically textured surfaces, which also has  $\text{TiO}_x$  thin films as the surface passivation and anti-reflection coating, is shown in Figure 9-6. Compared with polished device, the textured device shows a 4 % reduction in the open circuit voltage and a 7 % drop in fill factor. The reduction in open circuit voltage may be attributed to the coating for textured structure is not as well as the coatings on polished surface. The quantum efficiency of the textured device is more flat than that of the polished one. It can be attributed to the reflection curves also shown on the right axis.

Figure 9-6: (a) Dark and light I-V curves and (b) external quantum efficiency and reflection curves for Si solar cells with  $\text{TiO}_x$  thin films as the surface passivation and anti-reflection coating on chemically textured surface <sup>[46]</sup>

### 9.3.3 Surface passivation

PCD method is useful for characterizing the near-surface regions of semiconductors. PCD measures an effective minority carrier lifetime given by

$$\frac{1}{\tau_{\text{effective}}} = \frac{1}{\tau_{\text{surface}}} + \frac{1}{\tau_{\text{bulk}}}$$

Where  $\tau_{\text{bulk}}$  is the bulk lifetime,  $\tau_{\text{surface}}$  is the surface lifetime,  $\tau_{\text{effective}}$  is the effective lifetime. The surface treatment will not change  $\tau_{\text{bulk}}$ , so any observed change in  $\tau_{\text{effective}}$  is correlated to a change in the surface electrical properties.  $\tau_{\text{effective}}$  is predominantly determined by  $\tau_{\text{surface}}$  for a thin sample region, and the bulk contribution does not need to be known.

The optical absorption coefficient for Si is  $2.5 \times 10^3 \text{ cm}^{-1}$  at a wavelength of 658 nm, and the light penetration depth ( $\alpha^{-1}$ ) is approximately 4  $\mu\text{m}$ . Hence, using  $\lambda = 658 \text{ nm}$ , the minority carrier lifetime is measured in a substrate region within 4  $\mu\text{m}$  from the

surface of the wafer. The measured properties should be heavily influenced by the characteristics of the surface.

The principle of PCD technique is based on excess carriers injected by the illumination pulse, which increase the conductivity of the Si by

$$\Delta\sigma = q(\mu_n\Delta n + \mu_p\Delta p)$$

where  $\Delta\sigma$  is the increase in conductivity (photoconductivity),  $q$  is the electron charge,  $\mu_n$  is the electron mobility,  $\mu_p$  is the hole mobility, and  $\Delta n$  and  $\Delta p$  are excess electron and hole concentrations respectively.

Assuming  $\Delta n = \Delta p$ , then  $\Delta\sigma$  is proportional to a change in  $\Delta n$  (or  $\Delta p$ ). If we also assume that the carrier decay time, governed by the carrier lifetime  $\tau$ , is given by

$$\Delta n(t) = \Delta n(0)e^{(-\frac{t}{\tau_{eff}})}$$

Then the slope of the semi-log curve of  $\Delta n(t) / \Delta n(0) - t$  plots would be

$$Slope = \frac{d \ln(\Delta n(t))}{dt} = \frac{\ln(10)d \log(\Delta n(t))}{dt} = -\frac{1}{\tau_{eff}}$$

Taking the linear portion of the plot gives  $\tau_{eff}$ . The voltage decay is proportional to the excess carrier density <sup>[109]</sup>. The initial decay of the PCD signal is linear on a semi-log plot and is representative of the surface component.

We studied the passivation effect of  $TiO_x$  layer by comparing with samples without any passivation layer and samples with  $SiO_2$  as passivation layer. The results are shown in Figure 9-7. Figure 9-7 (a) shows the passivation on n-type wafer, Figure 9-7 (b) shows the passivation on p-type wafer. The near surface life time is 60  $\mu s$  for n-type wafer without any passivation. The  $TiO_x$  layer increases the near-surface carrier lifetime

to 80  $\mu\text{s}$  for both n-type and p-type wafers. Therefore,  $\text{TiO}_x$  layer effectively passivated the Si surface. It is not as effective as  $\text{SiO}_2$  passivation layer for n-type wafer. The passivation could be due to the charge accumulation at the Si/ $\text{TiO}_x$  interface <sup>[110]</sup>.

(a) N-type wafer

(b) P-type wafer

#### **9.4 Summary**

In summary, we have successfully demonstrated  $\text{TiO}_x$  thin films as surface passivation and anti-reflection coatings for silicon solar cells. We report the results of  $\text{TiO}_x$  thin films as anti-reflection coating and surface passivation layers for polished as well as textured silicon solar cells. Silicon solar cells fabricated with  $\text{TiO}_x$  thin films for ARC and surface passivation showed an efficiency of 15.7 %. Surface passivation quality is evaluated by near-surface lifetime technique .The  $\text{TiO}_x$  layer increases the near-surface carrier lifetime to 80  $\mu\text{s}$ .

## Chapter 10.     **Summary and future work**

### **10.1 Summary**

In this dissertation, we explored a novel  $\text{TiO}_x$  material for low cost photovoltaic applications. The fundamental properties, including optical, electrical, structural, and morphological were studied. The  $\text{TiO}_x$  photochemically activated protection mechanisms for organic solar cells were investigated using electrical and chemical methods. Laser beam induced mapping technique was used to explore the local degradation of the devices. Cs and Fe doping of the  $\text{TiO}_x$  thin films were examined for improving the material properties.  $\text{TiO}_x$  material has also been demonstrated to be an effective anti-reflection and passivation layer for Si solar cells. The passivation effects were evaluated by near surface carrier life time measurements.

Refractive index of the  $\text{TiO}_x$  thin films was calculated using a three-layer model incorporating the ellipsometrical method. At the wavelength of 600 nm, the obtained refractive index ranges from 1.77 to 2.57 depending on the annealing temperature. The range can be explained by the changes in the crystalline structure, the difference of surface morphology and the increase of the packing density of the films as indicated by SEM, AFM and XRD results. The high refractive index and high transmission in the visible spectrum indicate sol-gel  $\text{TiO}_x$  films may be useful in optical thin films applications as antireflection layer.

The bulk resistivity of as-deposited  $\text{TiO}_x$  thin films was found to be  $1.5 \times 10^7 \Omega\cdot\text{cm}$ . Thermal annealing decreases the resistivity. The resistance of Al/ $\text{TiO}_x$ /ITO structure is stable for temperature from 20 °C to 140 °C.

We studied the stabilization behavior of P3HT/PCBM organic solar cells under air and UV irradiation using  $\text{TiO}_x$  protection layer. Significant improvements were observed with  $\text{TiO}_x$  layer protection from the data on the degradation of solar cell performance under air and UV exposure. The protection mechanism was also investigated by transmission IR and ESR spectroscopy. The results of this study suggest a photochemically activated protection mechanism. The photooxidation of the bound organic moieties causes oxygen gas scavenging when excited by UV photons. Around 10% UV energy in the standard solar irradiation was absorbed by the  $\text{TiO}_x$  layer.

2D images of the local photocurrent in the cells with and without  $\text{TiO}_x$  protection layers were obtained by LBIC measurements. Degradation spots were observed in various organic solar cells. Enhancement of the degradation spots was observed from all the cells, but the shrinkage of the active area from the edge was observed only in the organic solar cells without  $\text{TiO}_x$ . The results show that the introduction of the  $\text{TiO}_x$  layer could effectively absorb water/oxygen from ambient air and protect the cells at the edge of the devices.

We explored the applications of these  $\text{TiO}_x$  thin films doped with  $\text{Cs}_2\text{CO}_3$  and Fe for organic solar cells applications. Initial results show that Fe doping could reduce the series resistance of the organic solar cells. Thus, the power conversion efficiency increases around 10% compared to devices with undoped  $\text{TiO}_x$ . The results of the effect of doped  $\text{TiO}_x$  films on organic solar cells parameters like efficiency, open circuit voltage, short circuit current and fill factor were presented. The variation of resistances for the organic solar cells with  $\text{TiO}_x$  material of different  $\text{Cs}_2\text{CO}_3$  doping concentrations was reported.

We have successfully fabricated silicon solar cells using  $\text{TiO}_x$  thin films for surface passivation and anti-reflection coatings. We made silicon solar cells with  $\text{TiO}_x$  on polished as well as textured surfaces. The devices showed an efficiency of 15.7 %, which is comparable with Si solar cells using  $\text{SiO}_2$  and  $\text{Si}_3\text{N}_4$  as passivation and anti reflection layers, respectively. Surface passivation quality was evaluated by the near-surface lifetime technique and we obtained a maximum value of 80  $\mu\text{s}$  for n-type Cz-Si wafers.

## **10.2 Future work**

$\text{TiO}_x$  material has been demonstrated as an effective optical spacer and protection layer, and the material properties have been studied and modified. However,  $\text{TiO}_x$  material may have further applications with new structures or dopants. For example, it could be used in organic solar cells on new textured structures to alleviate the non-conformal problem. The stability of organic solar cells may be improved further using a combination of  $\text{TiO}_x$  and a stable hole transport layer other than PEDOT: PSS. The carrier transport and passivation effects may be improved through other dopants. We will discuss future work in the following sections:

### **10.2.1 Optical absorption enhancement by textured structure**

As discussed in the previous chapter, in P3HT: PCBM material system, there is a mismatch between optical absorption length ( $>100$  nm) and average distance for charge transport ( $\sim 10$  nm). It is highly desired to develop new methodologies that can enable efficient optical absorption in films thinner than the currently used (100 nm) and to reduce series resistance.

Textured substrates for improved light trapping are common in traditional inorganic solar cells. They utilize the effect of multi-reflection by roughening the entrance interface and randomizing the light propagation direction, which results in a much longer optical path length at the surface and hence a substantial absorption enhancement. Realizing organic solar cells on such topographies provides an efficient way to achieve light-trapping without compromising the electrical characteristics.

However, textured substrates have not been successfully applied to polymer-based organic solar cells. Enhancement in optical absorption was demonstrated in different patterning schemes, for example, grating-type organic solar cells<sup>111</sup>, V-shape organic solar cells built by mounting two cells together,<sup>112</sup> microprism substrates,<sup>113</sup> and azopolymer-based sub-micrometer topography substrate<sup>114</sup> have been reported. Efficient OSC cells could not be realized due to the processing bottlenecks of solution-processing nano-scale thick and conformal active layers on topographical surfaces. Attempts to spin-coat active-layer on textured substrates led to over filling of the valleys and shunts at the crests, which severely affected the device performance, as shown in Figure 10-1:

Figure 10-1: Non-conformal coating on top of textured substrate

It has been demonstrated<sup>[115]</sup> that a  $\text{TiO}_x$  spacer layer benefits a thin active layer, but it is less effective with an optimized thick active layer. If a  $\text{TiO}_x$  spacer layer were

used in organic solar cells coated on the textured surface, as shown in Figure 10-2, it is possible to get high efficiency in both the thin and thick area. In the thick coating area, the device keeps high efficiency. In the thin coating area, the spacer layer will enhance the optical absorption; therefore the efficiency will increase the efficiency. The overall efficiency of the cell may not decrease.

Figure 10-2:  $\text{TiO}_x$  on the top of the non-conformal coating on textured substrate

### 10.2.2 Further improvement from degradation

In typical OSC devices, PEDOT: PSS is commonly used as the hole transport layer. But the use of PEDOT: PSS induces numerous problems; among them is its tendency to absorb atmospheric water, which contributes to significant degradation or performance reduction of the device. Therefore, alternatives to PEDOT: PSS have been intensively studied, such as graphene oxide <sup>[116]</sup>, nickel (II) oxide (NiO) and so on. <sup>[117]</sup>

Soo Young Kim et. al demonstrated that OSC with ~3 nm graphene oxide hole extraction layers exhibits increased power conversion efficiency<sup>[116]</sup>. J. R. Manders et.al fabricated high efficiency OSCs with efficiency comparable to PEDOT: PSS-based devices using nickel oxide hole transport layers <sup>[117]</sup>. The unencapsulated NiO-based

devices show a 300% improvement over PEDOT: PSS-based devices in the maintaining >50% of the original efficiency with time.

We demonstrated that  $\text{TiO}_x$  extends the lifetime of the OSC with a PEDOT: PSS layer. It could effectively prevent degradation from the edge of the OSC, which is probably due to water absorption of the PEDOT: PSS layer.

The stability of the device with  $\text{TiO}_x$  and nickel oxide instead of PEDOT: PSS may be improved further because of the double protection from both sides of the active layer, as shown in Figure 10-3. It would be of interest to test this new device. The protection of combining  $\text{TiO}_x$  and graphene oxide could also be explored.

Figure 10-3: Proposed structure of device with  $\text{TiO}_x$  and nickel oxide protection layer

### 10.2.3 $\text{TiO}_x$ material property tuning

We explored the effects of Cs and Fe doping on the performances of the organic solar cells. It has been demonstrated~~Error! Bookmark not defined.~~ that the properties of metal oxides can be tuned through the addition of various dopants and processing methods other than Cs and Fe doping.

Several approaches for  $\text{TiO}_2$  modification have been proposed: metal-ion doped  $\text{TiO}_2$  (using transition metals: Cu, Co, Ni, Cr, Mn, Mo, Nb, V, Fe, Ru, Au, Ag, Pt) <sup>[118,119,120]</sup>, non-metal doped- $\text{TiO}_2$  (N, S, C, B, P, I, F) <sup>[121, 122, 123]</sup>, and  $\text{TiO}_2$  doped with an upconversion luminescence agent <sup>[124]</sup>. The introduction of dopants offers a convenient method for producing functional materials.

Therefore, it is of interest to explore the effects of other dopants that may facilitate the carrier transport and the lifetime of the organic solar cell devices. Also, the passivation for the Si solar cell by  $\text{TiO}_x$  material may be affected by the doping. Doping induces different energy levels and charge compositions, which will affect the passivation.
